Freshwater systems are intimately tied to surrounding terrestrial systems, so conserving one requires conserving the other. Despite numerous efforts to protect watersheds or establish drinking water projects, few programs address the link with protected areas that were often created to protect water sources (McAlpine and Wottom, 2009; Nel *et al.*, 2009). While evidence suggests that it is more cost effective to protect than mitigate, the costs of watershed management have been almost universally neglected in water pricing. Worse still, these costs have not been evaluated against operational costs for water treatment or investment costs for new infrastructure. Recent evidence of shrinking clean water supplies and perceived water insecurity have made businesses and water utilities look at freshwater as they never have before: a valuable good that is produced, sold, and consumed and deserves investment. Increasingly, this investment is in the form of payment for ecosystem services (PES) projects to conserve freshwater systems.

Ecosystem Services and Payment for Ecosystem Services: Rapidly Expanding Conservation Approaches

In the latter half of the 1990s, researchers began using ecosystem service values to demonstrate the importance of natural capital (e.g., Costanza *et al.*, 1997), and with the publication of the Millennium Ecosystem Assessment (MA, 2005), the importance of biodiversity to secure livelihoods became increasingly evident, particularly through the delivery of ecosystem services – the benefits that nature can provide to people (Daily, 1997). In the past decade, more studies have looked at ecosystem service values and at the biodiversity values either directly associated with ecosystem services such as the economic benefits to pollination from conservation (e.g., Ricketts *et al.*, 2004) or the indirect, all-inclusive values such as the economic benefits and costs avoided by not creating protected areas (e.g., Bezaury-Creel, 2009). These have led to an increasing understanding of the relationship between biodiversity conservation, ecosystem services, and human well-being.

Inevitably, ecosystem service approaches to biodiversity conservation will require trade-offs that might imply that the conservation of one service is done at the expense (degradation) of another (e.g., Heal *et al.*, 2001; Pereira *et al.*, 2005; Rodríguez *et al.*, 2005, 2006). Of particular interest is the possibility that the recent emphasis on ecosystem services could actually detract from biodiversity conservation. For example, if projects are designed and managed with special attention to how people benefit, will that take attention away from biodiversity (Kareiva *et al.*, 2008)? Naidoo *et al.* (2008) found that locations selected for conserving ecosystem services would conserve only 22–35% as many species as locations selected for preserving biodiversity. What's more, only 16% of World Bank biodiversity-focused development projects resulted in a win–win for biodiversity and human well-being (Tallis *et al.*, 2008). That said, optimizing an ecosystem for one or a few services can prove beneficial provided the ecosystem can function as a whole (e.g., Tallis and Kareiva, 2006). As such, ecosystem services are one of many biodiversity conservation approaches.

Despite such trade-offs, ecosystem service approaches to conservation confer advantages, not the least of which is providing opportunities for conservation in new areas. Thinking in an ecosystem services framework can broaden the scope for conservation by expanding where we view conservation opportunities and what those opportunities are (Tallis *et al.*, 2009;

Goldman *et al.*, 2008). Additionally, that approach can diversify stakeholder interest in and funding streams for conservation (Goldman *et al.*, 2008), so it is one of many useful approaches for conservation. While there is still uncertainty about what factors are likely to contribute to successful ecosystem service projects (Perrot-Maître, 2006; Asquith and Wunder, 2008; Engel *et al.*, 2008; Jack *et al.*, 2008; Daily and Matson, 2008) and debates about their use continue (e.g., Goldman and Tallis, 2009), these approaches continue to proliferate.

Ecosystem service projects can take a wide variety of forms and serve a variety of functions (Tallis *et al.*, 2009), but in applied conservation, PES projects are widely touted as an innovative finance mechanism (Salzman, 2005; Wunder, 2007; Jack *et al.*, 2008). In the last decade, PES schemes have received considerable attention (e.g., Landell-Mills and Porras, 2002; Pagiola *et al.*, 2007; Jack *et al.*, 2008; Sommerville *et al.*, 2009) with their focus on providing financial incentives to land owners or managers whose conservation actions benefit others when those benefits would otherwise not be compensated (Sommerville *et al.*, 2009).

Payment for watershed services (PWS) projects, a subset of PES approaches, are a significant portion of ecosystem services schemes (many others relate to carbon) and often involve water users paying "suppliers" for the delivery of clean, consistent water supplies (Brauman *et al.*, 2007; Krchnak, 2007; Asquith and Wunder, 2008; Porras *et al.*, 2008). Numerous case studies of these approaches exist in the developed (e.g., Perrot-Maître, 2006) and developing (e.g., Stanton *et al.*, 2010) world. In 2002, there were only 41 proposed and ongoing PWS schemes in developing countries (Landell-Mills and Porras, 2002), but the number more than doubled in 6 years as a recent review documented 50 ongoing, eight advanced proposals, and 37 preliminary proposals (Porras *et al.*, 2008). Both freshwater ecosystems (wetlands, aquifers, rivers, and lakes) and terrestrial ecosystems provide hydrologic services (MA, 2005) and help to regulate the quantity and quality of water accessible to people, but the value associated with this service is difficult to capture; there is no easily obtainable market value. Water funds are a mechanism that uses the value of these hydrological services to enable biodiversity conservation. **Figure 1** is the map of ongoing and proposed water funds.

Water Funds: Protecting Biodiversity Through Ecosystem Service Payments

The Nature Conservancy (TNC), in collaboration with numerous partners, has successfully replicated a series of PES projects called water funds across Latin America. In these funds, payments from water users help protect the ecosystems that provide important hydrologic services and help improve management of working landscapes to ensure regular supplies of clean water. TNC has partnered with the Inter-American Development Bank (IDB), the Global Environment Facility (GEF) and FEMSA Foundation to improve the water funds model, to further replicate it, and to explore new sources of private and public funding for watershed conservation and management. The US Agency for International Development (USAID) has been another critical partner in replicating water funds, particularly in Ecuador.

Through water funds, TNC has more than matched the rapid advancement of watershed-based ecosystem service payment schemes in the global developing world in just one region (the Northern Andes) using just one project approach. In addition to funds not supported by TNC, today there are about 45 TNC-supported water funds in some stage of development in LAC (**Figure 1**; **Table 1**) ten of which are operational. What makes the water fund model so successful? Water funds are driven by water users, and the approach has the potential to be successful in a variety of political and institutional settings throughout the world. They have many of the elements for success identified in similar schemes (Porras *et al.*, 2008; Landell-Mills and Porras, 2002) but they go beyond the basics to become truly participatory, long-term, adaptable, multi-institutional, sustainable watershed conservation projects that with strong leadership and advocacy set them apart from the others.

History of the Water Fund Concept

About 80% of the water for the city of Quito, Ecuador (nearly two million people) comes from three protected areas and their buffer zones: Cayambe-Coca Reserve, Antisana Reserve, and Cotopaxi National Park. These areas contain about 5% of Ecuador's land area, include headwaters of more than 20 rivers and six larger watersheds, and provide critical habitat for many of Ecuador's bird and mammal species, but a variety of activities threaten this biodiversity and the availability of the clean, regular water supply. These threats include insufficient budgets to adequately control and conserve protected areas and buffer zones to prevent ecosystem conversion, illegal logging, and deforestation, among others. Much of the pressure on the land is from the people living in the watershed, as they depend on natural resources for their livelihoods. Available productive land is diminishing as soils lose nutrients, forcing families to move up the watershed into the natural ecosystems – a mixture of forest and *páramo* (high altitude grasslands) – that are the key hydrologic regulators of the system. Conversion means diminishing water services to people downstream, but keeping watershed communities out is unjust and unsustainable.

In the late 1990s, with the results of the USAID- and Fundación Antisana-funded SUBIR I and II projects in hand, TNC approached the mayor of Quito to demonstrate that protecting Quito's watersheds was crucial if citizens were to continue to enjoy the same regular supply of clean water in the future. TNC wanted to create a finance mechanism for

watershed conservation, and then Ecuador Program Director, Roberto Troya, obtained the support of the mayor, the municipality and the Quito water company (Empresa Municipal de Alcantarillado y Agua Potable de Quito – EMAAP-Q – the key water user) to do so.

The financial approach was carefully evaluated and selected because it was ecologically sustainable, legal, politically viable, efficient, and participatory (Krchnak, 2007). In January 2000, it was decided that voluntary donations from stakeholders would go into a trust fund that would form the financial basis of the water fund. The Quito Water Conservation Fund – Fondo para la Conservación del Agua or FONAG – was thus created as an endowment fund now receiving money from government, public utilities, electric companies, private companies, and nongovernment organizations. The donations were invested and managed by an independent organization through a trust, and initially, only the interest was used to fund activities. Over time, the financial model has shifted; now some contributions go into the endowment and some immediately finance conservation activities.

FONAG initially had two main members: TNC and EMAAP-Q. Other water users have since joined such as the Quito Electric Company (La Empresa Eléctrica de Quito – EEQ) in 2001 and private organizations including a beer company (Cervecería Andina) in 2003, the Swiss Agency for Development and Cooperation (COSUDE) in 2005, and a water bottling company (Tesalia Springs Co.) in 2005. Incentives for participation vary but are complimentary. The main incentive for EMAAP-Q and the other major water users was avoiding or reducing future costs for water treatment and

supply, functions provided by the conserved ecosystems. For TNC, the incentive was long-term financing for conserving protected areas (Goldman *et al.*, 2010a).

FONAG is governed by a board of directors comprised of water users who have contributed to the fund. The board approves the annual operational plan and reports, conducts audits, and reforms the bylaws. It also has a technical secretariat that acts as executive director.

In 2004, TNC invited the mayor of Quito to visit the PES mechanism in New York City, the example upon which FONAG was created. As a result of this visit, the mayor helped support and pass a municipal ordinance dedicating 2% of water fees to FONAG. TNC and the FONAG secretariat have been instrumental in helping explain and explore the benefits nature can provide to people, in this case, hydrologic services. USAID was another critical component of FONAG's success and has been a key player in strengthening FONAG and in financing a variety of the fund's activities.

The water fund concept has been improved dramatically since FONAG. Several have used cutting-edge science to meet challenges like the funds in Bogotá and the Cauca Valley of Colombia and in the Paute watershed near Cuenca, Ecuador. New users like major hydropower companies and big agricultural producers are involved and are beginning to understand and learn about the value of nature to their business operations. TNC has proposed a model and a business plan to replicate water funds in new places around the world.

The Institutional Workings of Water Funds

Clean water is a basic human necessity: not only do people require it for drinking, but many industries require it for production including everything from electricity to beer. In many watersheds, this life-supporting service comes from surface flows and aquifers. Nowhere is this truer than in the Northern Andes region of South America. Here, surface flows from high altitude head waters supply water to diverse users most notably several large cities (e.g., Bogota and Quito), hydropower companies, and in some cases, agricultural producers. These users have a vested interest in maintaining clean, regular water flows at the lowest cost and in managing supply risks. Water funds emerged from these concerns.

Water Funds are an innovative way to pay for nature's services – clean freshwater and biodiversity – by investing in conservation projects that protect the healthy habitat from which the services derive. Each water fund has its own set of objectives and goals, but in general, they invest to: (1) improve or maintain water quality and water quantity for downstream users; (2) maintain regular flows of water throughout the year; (3) maintain or enhance natural ecosystem biodiversity, both freshwater and terrestrial; and (4) improve or maintain human well-being and quality of life for upstream human communities (Goldman *et al.*, 2010a).

Historically, water flows and water cleanliness have been naturally regulated by predictable precipitation patterns and natural vegetation, but deforestation and the degradation of natural ecosystems, increased human demand for water, and a changing climate are all threatening and disrupting the ability of ecosystems to provide these services. Thus, water purification and storage services are now increasingly provided by water filtration plants or regular dredging of reservoirs to remove unwanted sediments. Water funds aim to restore or maintain nature's ability to provide these critical hydrologic services. In the long run, it could be cheaper and more sustainable than investing in business as usual, that is, gray infrastructure.

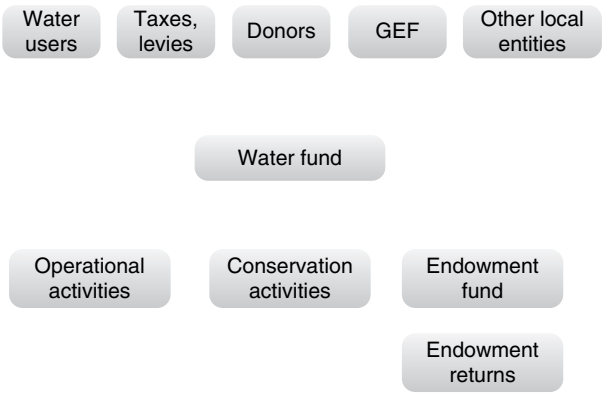

Figure 2 Water fund general model including financial flow and operational process. A wide variety of water users and other donors have invested money in water funds. Depending on the fund, portions of investments are directly invested in operational activities and conservation activities (protection and restoration) while the rest of the fund money is invested in an endowment fund. Capital from the endowment fund similarly funds operational and conservation activities.

Figure 2 summarizes the basic water fund model. The funds attract contributions from water users such as water utilities and local industries. These contributions build the funds' capital, including an endowment fund. In turn, endowments are invested in a wide range of assets (e.g., money market, bonds, and stocks) and the revenue generated from those investments provides long-term, secure funding for conservation projects like creating and strengthening protected areas, helping neighboring landowners switch to conservation-friendly management practices, paying for conservation easements, and financing environmental initiatives for local communities. Species benefit from having larger and better protected territories, communities benefit from a healthy watershed and improved land management, and large water users benefit from the resulting reduced water treatment costs. In addition, investments in watershed management reduce the risk of future clean water shortages that promotes long-term economic growth. With watershed conservation as a common objective, water funds create a governing body often bringing together public and private partners to manage it.

Investing in Watersheds: Providing the Hydrologic Services

Water funds invest in nature and in people by resolving potential conflicts between the resource needs of watershed communities and the conservation needs for water-service supply. Thus, investments focus on:

1. Managing public protected areas; and
2. Implementing best management practices on productive systems.

Ensuring good conservation management and providing incentives to conserve and restore natural ecosystems can provide long-term protection for the watershed but only if the incentives are sufficient to compensate people for any negative impacts.

Public Protected Area Management

The Northern Andes Region contains 20% of the World's biodiversity in an area that covers only 0.2% of the world's surface; 17% is protected and a relatively intact mixture of native forests and *páramo*. However, growing demand for land and access to resources to support livelihoods is increasingly threatening protected areas, and the level of government investment is not sufficient. For example, in 2005 according to the Ministry of Environment in Ecuador, there were 31 legally declared protected areas and there was a budget shortfall of ~$9.5 million (all $ as USD unless otherwise stated). For even the most basic management the gap was still ~$3.6 million. Despite numerous efforts, few programs address the link between managing protected areas and drinking water (Echavarria, 2002; Benitez *et al.*, 2010). *Páramo*, in particular, is a crucial water regulator; disturbance can damage or destroy its hydrologic functioning (Buytaert *et al.*, 2006, 2007). Water funds do address the link between drinking water and protected areas and can supplement budgets by cofinancing park guards, creating community-based ecotourism programs, and improving infrastructure management (**Table 2**). Park guards paid by the water fund are from the local communities ensuring community participation and acceptance, and providing a stable source of income for participating families.

Implementing Best Management Practices

In the watersheds, families rely on crop and ranchlands for income in and around protected areas. Managing these lands can have major impacts on water quality, the timing of flows (particularly floods), fires, and freshwater biodiversity. Water funds seek to minimize these impacts by providing direct and indirect payments to families for land management that includes setting aside conservation areas (e.g., fencing off riparian areas and headwaters), restoring and revegetating priority areas, silvopastoral management (e.g., live fences, forage plants, and rotating pastures), creating agroforestry systems, and/or creating tourism facilities (**Table 2**).

Specific conservation management practices supported by the water funds will vary by location, but investing in land management is essential for providing ecosystem services.

Table 2 Conservation activities of water funds

Activities	*Description*	*Type of strategy*	*Relation with water and biodiversity*		
			Area maintenance (conservation)	*Best practices*	*Restorations*
1. Public protected area management plan implementation					
1.1. Co-finance park guards	Improve control of high-risk conservation areas	Threat abatement	■		
1.2. Community-based eco-tourism programs	Reduce threats to buffer zones through income substitution	Threat abatement	■	■	■
1.3. Improve infrastructure management	Support best practices on management of current and new infrastructure in the park	Threat abatement	■	■	■
2. Best practices at the farm or productive unit					
2.1. Set aside conservation areas	Environmental payment for areas set aside for conservation on farmland: along streams, headwaters or forest connectivity	Conservation	■		
2.2. Set aside areas and restoration	Restoration payments and future environmental payments for areas set aside for conservation and restoration	Conservation			■
2.3. Silvopastoral systems	Improve productivity of farm with more environmentally-friendly cattle ranching practices such as live fences, forage plants, rotation of pastures	Best practices		■	
2.4. Agroforestry systems	Introduce environmental practices in the farm	Best practices		■	
2.5. Tourism facilities	Income substitute for land use practices	Conservation	■		■

These services can benefit the landholder (by enhancing soil stability and nutrient cycling), other people in the watershed (by providing clean and consistent water flows), as well as the broader ecosystem (by protecting habitat and biodiversity). Changing management practices is not, however, without cost. Restricting access to fertile soils in natural ecosystems and encouraging conservation management on productive lands involves trade-offs. Families are left with less land, so adequate, appropriate compensation is necessary.

The Payments: Compensating Impacts

Water funds must be flexible as they are established in geographically diverse places and in different legal and institutional settings. This includes the type of compensation provided to watershed communities. In the Northern Andes, indirect payments and livelihood investments have worked best. Indirect payments are in the form of materials and training to improve land management such as supplies for fencing and seeds for revegetation. Ideally, conservation management will enhance farm/ranch productivity by producing on-farm ecosystem services such as soil stabilization and enhanced soil fertility, but these benefits will not be immediate and are not guaranteed. In the shorter term, conservation management agreements include livelihood investments such as environmental education programs, alternative income sources like guinea pig farms, alternative food sources like organic vegetable gardens, and expanded capacity for production like building a milk bottling plant in the community to reduce shipping costs and payments for outside bottling fees, among others. As described later (*see* The Case of Brazil), in addition to indirect payments, Brazil uses mostly direct payments to landowners to compensate them for the opportunity costs of their traditional land uses.

Financial Sources and Management

Flexibility is also required in financial management, as are transparency and longevity, to ensure success under different legal and institutional frameworks. The core financial mechanism is a trust fund or endowment fund (**Figure 2**). This unique fiduciary structure involves an independent financial institution. A trustee (nonpartisan) manages and distributes payments to recipients (e.g., watershed communities and/or park guards) based on decisions made by the trustors, that is, the water fund board that generally comprises the main water users and other stakeholders. National and regional rules and regulations dictate the preferable investment scheme for the fund (private, nongovernment, etc.). All the trust funds have long-term contractual arrangements explicitly defining their use.

Water user contributions to the trust create a principal that accrues interest revenue for conservation projects. Ideally, the principal is untouched and only the interest is used. TNC and partners have learned, however, that in order to secure more partners and more contributions, at times it is important to use part of the principal in the first few years to demonstrate tangible progress as interest takes time to accumulate (**Figure 2**). Thus, the initial financial arrangement must include what percentage of the fund, if any, can be used. Some of the water funds, Fondo del agua para la conservación de la cuenca del río Paute (FONAPA – Water Fund for the Conservation of the Paute river watershed), for example, have designated a portion of the trust to go directly to conservation activities. This makes sense in smaller watersheds that are less likely to have large capital investments earning significant interest in a reasonable time.

Water funds can be financed from a variety of private and public sources including the following:

- *Water users* (*e.g., water utilities, bottling companies*): potentially the largest beneficiaries, the users are also often the largest financial contributors.
- *Citizens:* a fundraising proposal for the Bogota water fund was to get donations from citizens through their water bills. Contributions from the general public (low contribution, high volume) can be a significant source of funding.
- *Taxes, levies, and public programs*: working with existing local regulations, taxes, fees, or special-purpose contributions can be a strong source of funding. In FONAG, a municipal ordinance requires the water company to direct 2% of tariffs to the fund. In countries such as Colombia and Brazil, water laws obligate water users, municipalities, and environmental regional authorities to invest resources in the watershed, and water funds have managed to capture their interest since they leverage other money, are participatory, and can function as implementation arms for public funding. In some cases, this might be an ideal revenue source for water funds.
- *Grants, international organizations, and private foundations*: funding from bilaterals, multilaterals, or independent foundations can play a strategic role in the first 2 years of a water fund by helping to establish it including funding feasibility studies. TNC has provided this support in the past. Grants are also used to fund specific activities in the conservation plan. USAID, for example, has been very important in supporting water funds in the Andean region.
- *GEF*: funding will be directed to critical start-up costs, specifically to the endowment fund, and will co-finance outreach and feasibility studies. In Brazil, money will be spent only on technical support and conservation activities.
- Financial returns generated from the endowment fund.

Revenue sources vary from one water fund to the next depending on a variety of factors such as the legal framework for water policy, private sector opportunities, environmental service provisions, and governance strategies. Based on current experience, the majority of funding will come from the public sector and from water users. Funding through grants, international organizations, and private foundations, while proportionately small, is essential in ensuring that the water funds have a solid foundation.

Governance

Water funds are governed not by a separate nonprofit or nongovernment entity; rather, they are governed by contractual partnerships which create a collaborative, stakeholder-based, decision-making board that elects and approves

a technical secretariat that calls meetings and implements decisions. In addition, the board can establish technical committees to help guide its investment decisions. The main contributors to the fund necessarily have a voice on the board, but noncontributors and indirect contributors can also participate. For example, in the Procuencas water fund in Zamora, Ecuador, the Ministry of the Environment, a noncontributor, has a seat on the board as their input and support is essential. In Tungurahua, Ecuador, numerous, important indigenous communities in the watershed will be affected by the water fund and have invaluable knowledge about the watershed, so the German Technical Cooperation Agency GIZ donated money in their names so they have representatives on the board. TNC contributes both directly and indirectly, and in many cases has a representative on water fund boards. In the Cauca Valley in Colombia, each of the nine watersheds that feed the East Cauca Valley has a grassroots, nonprofit organization that has been working with the communities for many years. The directors of these organizations have seats on the technical committee to ensure community input.

The board sets priorities and makes decisions on investments and approves activities, but a lesson learned from FONAG was to ensure a scientific or technical basis for those decisions; thus, most are now based on feasibility or analytical studies and often on advice from a technical committee composed of scientists and engineers. The overall obligation of the board, with input from the committee(s), is to create and implement a strategic and an operational plan that include specific objectives and the means to achieve them.

How is a Water Fund Created?

While there cannot be a single formula for creating a water fund given the diversity of their features, there is a set of general steps that should be followed to establish a successful one. These steps are the result of a decade of lessons learned by TNC in replicating, improving, and advancing funds across Latin America (see Calvache *et al.*, 2012 for more detail).

Step 1: Can We Even Think About a Water Fund Here?

The first step is to determine if the right service users and service providers exist in the same area. This requires an ecosystem services assessment to determine if specific areas for generating the hydrologic services upon which a specific set of water users depends can be defined. There must be an explicit, measureable relationship between a specific area, the services the ecosystems in the area can provide, and the stakeholders in the area. Three important questions guide this step: (1) What is or are the service(s) that the water fund will prioritize for protection, conservation, restoration, and where is the long-term opportunity? (2) What is the area of influence for generating these services? and (3) Who are the key water users interested in these services, what is their interest, and how might the value of these services be internalized in their cost-benefit analyses? This type of work is best done by establishing a core working group that includes a main water user when possible.

Step 2: Will a Water Fund be Successful Here and How?

A water fund will most likely be effective if technical, financial, and legal studies are conducted beforehand to demonstrate the importance of the water fund to water users and to provide information for setting investment priorities if and when the fund is created. Determining what studies are needed is best done by creating a working group that includes the key stakeholders identified in Step 1. Work can then be divided among the participants. The detail and depth of the studies will depend to a great extent on available data and resources, but they should attempt to answer the following questions: (1) What is the demand and supply status of current hydrologic services? (2) What are the potential benefits or impacts – environmental and socioeconomic – of the water fund? (3) Where are priority areas for water fund investments? (4) What is the cost of maintaining or improving hydrologic services? (5) How will the provision of hydrologic services change as land use and climate change? and (6) What services other than hydrologic services can the water fund maintain? There are a growing number of tools (e.g., InVEST, SWAT, and ECOSAUT) to analyze the feasibility of a water fund and the potential impacts of its investments.

A final critical study is a legal and institutional assessment/analysis. Water funds ideally need to be transparent, independent, and permanent. An institutional analysis can help to identify legal hurdles and opportunities and to define the most appropriate financial and governance structure for the fund given the particularities of the country. National, regional, and local laws are all important to consider and follow in water fund design.

Step 3: Designing and Negotiating the Fund

With the stakeholder analysis and the feasibility studies in hand, the structure of the fund can be designed, contracts can be negotiated, the governance mechanism can be determined, administrative principles can be defined, and a contact can be signed. As water funds involve stakeholders from a wide variety of institutions, it is essential to have a clear definition of roles and responsibilities. The structure should be specified in a contract that formalizes the partnership. From experience, TNC has found that a useful structure is the previously described board of directors, technical secretariat, and technical committee(s). The board is a formal public–private partnership working under a mutually agreed, legal contract to ensure that each stakeholder has a role and the obligation and incentive to carry it out.

Finally, a process for handling administrative details must be determined. These include managing fund activities, the money in the fund, and other administrative matters that arise during formation and implementation.

Step 4: Details, Details, Details

Taking into account the studies in Step 2, the basic components that will allow the fund to achieve its social, environmental, economic, and institutional goals are then decided. The goal is to establish the first board of directors that will then appoint the technical secretariat. In addition, a

technical committee should be created to help guide decision making.

After these entities are functioning, the board should develop a strategic plan and a financing plan. The strategic plan lays out the basic components of the fund's operational plan that should reflect the priority areas and activities in the feasibility assessments. The strategic plan should highlight the objective of the investments, the goals and how they will be achieved, a timeline, and costs. Fundraising is a critical part of water funds particularly to finance current activities, and bringing more water users into the fund can increase the amount of money in the trust thereby enhancing sustainability.

Step 5: Activities Begin

Operationalizing the fund means executing the plans created in Step 4, that is, implementing the proposed investments and all the activities needed to achieve the goals. Execution is mainly the responsibility of the technical secretariat, but this should be supported by the technical committee that can provide advice and suggestions to improve implementation.

Actual implementation means further prioritizing activities for investment with a view to maximizing efficiency – achieving the greatest impact for least cost. Scenario-based, land-use change analyses can help determine the best activities for achieving the goals. The major activities implemented thus far by water funds have been described previously.

The financial management plan created in Step 4 should include goals and a timeline for acquiring future funding and for capitalizing the trust. Implementation includes launching communication and fundraising plans. Interest in participating in a fund can increase or decrease, so it is important to constantly attract new donors and participants.

Finally, a plan should be developed to disseminate results beyond just the stakeholders in the water fund. This can often be done by contracting a marketing and communications firm. Fundraising can also be done by contracting an appropriate organization.

Step 6: Evaluating and Monitoring

A final, but very important, step is to monitor and evaluate outcomes to ensure the goals are being achieved and to promote adaptive management. A monitoring plan is a tool to help maintain and expand the technical and financial support for the water fund effort. It should cover socioeconomic, biophysical, institutional, and economic impacts. Monitoring outcomes can help to do the following: (1) ensure activities implemented are achieving desired goals; (2) make adaptive management possible allowing for changing and adjusting activities; (3) improve communications about the fund's activities and benefits; and (4) improve water fund transparency.

Examples of Water Funds: Ecuador and Colombia

As described previously, water funds are flexible ecosystem-services-based payment mechanisms adapted to different localities, regions, and countries. The following are two examples of water funds that have succeeded in different contexts. FONAG in Quito, Ecuador was the first water fund and is now demonstrating its impact. The Water Fund for Life and Sustainability – Fondo de Agua por la Vida y la Sostenibilidad – FAVS in Colombia is a water fund in the Cauca Valley whose water users are an association of sugarcane farmers.

FONAG – Quito, Ecuador

Previously we described FONAG; here we focus on outcomes. In 2000, FONAG had $21,000 invested in the trust fund – money from EMAAP-Q ($20,000) and from TNC ($1.000). By 2008, the trust fund had grown more than 250 fold to about $5.4 million and is now (2011) nearly $9 million. In 2008, this endowment yielded about $800,000 in interest to spend on conservation projects (FONAG 2008). In 2007, FONAG, with the support of its board members, helped to pass a municipal bylaw requiring the Quito water company (EMAAP-Q) to provide 2% of its revenue to the water fund (an increase from the initial 1% commitment).

FONAG was initially structured so that only endowment interest was used on conservation activities along with other money leveraged by the fund but not invested in the endowment. These investments were often substantial. From its initiation through 2008, $7.1 million was donated to FONAG as matching funds from a variety of other donors. USAID, in particular, has been one of the most important supporters of FONAG throughout; other donors include InWEnt – Capacity Building International, Germany; IDB, and EcoFund (FONAG 2008). This past year, the board decided to change the financial model and in the future, 30% of funds will be invested in implementing current and future activities and 70% will remain in the endowment.

FONAG uses the revenue from the water fund to finance various programs and projects. The programs currently underway are controlling and monitoring conservation areas, restoring natural vegetation, environmental education and outreach, training in watershed management, communications, integrated watershed management, and hydrological monitoring. The main beneficiaries of the activities are the communities close to the water sources. They receive permanent support from FONAG through various programs. From 2000 to 2010 FONAG has achieved the following:

- helped to conserve the watersheds that provide 80% of Quito's water (population of about 2 million);
- had a positive impact on 500,000 ha/1.2 million acres of land;
- enrolled 30,500 children in environmental education programs;
- enriched standing forest to improve forest density and quality on ~600 ha of land/year from 2006 to 2010;
- reforested 2033 ha/5023 acres of land with over two million trees;
- hired, trained, and salaried 11 park guards from local communities to help conserve protected areas; and
- engaged over 200 families in community development projects in rural basins.

Recent monitoring and evaluation projects have helped to demonstrate FONAG's impact. By analyzing the biodiversity of conservation areas supported by water fund investments and comparing them to areas with no such investments and a "pristine" reference site, it was found that the species composition of water fund-supported conservation areas are similar to the reference site but differ considerably from areas without water funds. There have also been reductions in grazing impacts and fire damage in several vast areas where the water fund supports protection. Finally, the analysis demonstrated that the conservation activities of the water fund helped maintain the ecology of the sites intact in an economically efficient manner (Boucher, 2011).

An analysis of water-related impacts revealed that waterways with water fund investments have greater ecological integrity, improved riparian and aquatic habitat quality, reduced erosion, and a more balanced temperature than waterways without fund investments. Additionally, the richness and diversity of macroinvertebrates in water fund waterways were greater than waterways with no water fund investments indicating better water quality and increased ecosystem integrity. These results were not true for each individual site analyzed (eight sites were compared with eight similar nonwater fund sites) which helped to demonstrate where adaptive management might be needed to ensure that more goal-appropriate activities are implemented in those areas (Encalada *et al.*, 2011).

In terms of impacts to the people living in the watershed, communities not affected by FONAG were compared socioeconomically with communities affected by the water fund across a number of variables. The results revealed that communities with FONAG interventions had the following: (1) a great diversity of plant and animal species in the watershed area; (2) greater investments in subsistence farming particularly in horticulture and meats that had lead to a reduction in expenditures by households in the market and increased food security; and (3) improved agricultural management. Communities impacted by FONAG also had a better understanding of their legal rights and had fewer community conflicts (Delgado and Mosquera, 2011).

As the oldest of the TNC water funds, FONAG has demonstrable results both in terms of actions implemented and outcomes. FONAG is only now developing studies to help prioritize investments; thus, the positive outcomes of the fund could potentially increase.

Fondo de Agua Por La Vida y La Sostenibilidad – Cauca Valley, Colombia

The FAVS water fund – Water for Life and Sustainability – in the Cauca Valley of Colombia lies near the city of Cali and serves a watershed that contains a huge number of sugarcane producers, an important export and domestic crop for the country. The water users are these sugarcane growers and about 900,000 people residing in cities in the watershed. As in FONAG, providing hydrologic services is dependent on conserving upstream natural ecosystems and managing the lands of rural watershed communities.

Led by TNC in June 2009, FAVS was launched by bringing together a variety of partners: ASOCAÑA (Colombia's sugarcane producers association), CVC (Corporación Autónoma regional del Valle del Cauca, the local environmental authority), Vallenpaz (a peace and justice organization), and nine grassroots organizations representing nine subwatersheds that feed the valley. Other stakeholders have since joined including the sugarcane growers association (Procaña), the technical branch of the sugarcane association (Cenicaña), and two other grassroots organizations representing two additional subwatersheds. In 2009, the fund contained $1.8 million in capital from the sugarcanes producers association (ASOCAÑA). In the first 2 years of its operations, FAVS raised more than $5 million from both the private and public sectors (UNICEF, PAVCO, Colombian Oil Company ECOPETROL, Regional Environmental Authority CVC, others). Current negotiations with the sugarcane growers association (Procaña) are likely to bring in an additional $2.3 million per year to the fund.

The principle objectives of FAVS are to increase the natural vegetation in the watersheds in order to maintain their hydrologic services, to conserve biodiversity, to provide water for consumption and for industry, to irrigate lands, to provide recreation, to generate energy, and to protect fishing resources. The Cauca Valley has the most productive sugarcane land in the world; damage to the region's forests and water resources threatens to reduce production significantly, which could cost the industry $33 million each year, according to the sugarcane producers association (ASOCAÑA) (based on TNC estimates of water yield and climate change that basically indicate that the length of irrigation cycles will decrease).

Activities in the watersheds that the fund is helping to support include isolating riparian areas to keep cattle and crops from riversides, protecting headwaters, reforesting and restoring landscapes, revegetating pasturelands, and conserving natural ecosystems. Ultimately the aim is to conserve and restore about 30,000 ha of land. In addition, through livelihood investments the water fund is promoting food security for local communities, environmental education, and capacity building to ensure sustainable production. FAVS aims to benefit 1500 families directly and to help provide water for 1.25 million people. To date, FAVS has spent more than $1.4 million on conservation projects: $0.1 million on the first water fund project; $ 0.6 million in the first call for proposals cycle and $ 0.7 million in the second proposal cycle. With these investments, FAVS has built more than 80 km of protected river fences; protected more than 87 headwaters; conserved over 250 ha of land through restoration and natural regeneration; converted more than 80 ha of critical land along streams to sustainable cattle ranching, supported the Las Hermosas Natural Park, supported nine schools by promoting environmental education, and supported at least 24 families.

FAVS has also helped to demonstrate the feasibility and importance of doing analytical studies to set priorities for water fund investments. In addition, it was the first water fund to test a methodology for ensuring that priorities for activities were based on cost and return on investment. The goal was to identify priority areas for FAVS investment, establish quantitative ecosystem service goals, and develop a portfolio of the most efficient activities. To achieve it TNC and partners used a watershed scoring process and a modeling tool called InVEST (Integrated Valuation of Ecosystem Services and Trade-offs),

developed by the Natural Capital Project (Tallis *et al.*, 2010). This evaluation involved several steps. First, a conservation activity (forest enrichment, reforestation, fencing, or silvopastoral practices) was assigned to each part of the landscape based on the behavior of landowners in the region and successful investments made in the watershed over the last 20 years. These assignments implicitly considered factors such as opportunity costs and land owners' willingness to change their activities (this willingness was evaluated in collaboration with the watershed grassroots community organizations). The landscape was ranked to highlight the places where possible conservation investments were likely to yield the greatest improvement in water yield and erosion control. Factors included in the ranking were those known to affect the hydrological response of the services such as slope, soil depth, distance to stream or water body, aspect, elevation and precipitation. Data from historic conservation investments in each watershed were used to estimate how much the proposed conservation activity in each location would cost (Goldman *et al.*, 2010b).

Then the landscape ranking and cost information were combined to select the highest ranked locations for each activity, tallying costs until the target budget level was met. The activities selected across the landscape formed the water fund's investment portfolio. This process was repeated for five budgets ranging from the level of investment currently committed by the fund ($10 million) to double that amount. With this set of investment portfolios as scenarios for future management, InVEST was used to estimate the ecosystem service returns from each (Goldman *et al.*, 2010b), specifically for erosion and annual water yield providing preliminary estimates of return on investment. The model provides a relative change (%) expected as spending progresses. One of the model's results demonstrated that for one watershed, erosion control benefits would increase from 1% in year 1 to 14% in year 5 based on water fund investments (The Natural Capital Project, 2011). Basically, InVEST helps to determine the most efficient investment portfolio for providing the two main services of interest: annual water yield and avoided sedimentation.

Work is now being done on this water fund to incorporate the impacts of climate change into the scenarios and the activity assessment. This impact assessment helps to determine if current activities promoted by the water fund are adapted for climate change and will allow for the design of activities to promote resilient ecosystems (Goldman *et al.*, 2010a). In particular, new ecosystem services maps incorporating suggested changes based on climate vulnerabilities were prepared and discussed with key stakeholders. These maps will complement the water fund portfolio in order to make sure that FAVS activities will be aligned with climate change analysis. This information was complemented with a local expert's suggestions in terms of the main problems related to land management and best practices. A complete conceptual model was developed for this workshop with local communities to help them to understand the links between land use practices and problems derived from climate change, and priority strategies for climate change adaptation were identified.

Not only did FAVS use studies to guide the investments of the water fund, but the fund also includes community members on the governing board. The watersheds that feed the Cauca Valley have suffered extreme levels of violence and disruption in the last decade; thus, providing the communities with a voice in how the fund operates ensures sustainability and equity. FAVS is also unique in that the main water users are agricultural producers, which demonstrates the potential for including a variety of stakeholders in water funds. A final characteristic that contributed to the fund's success is that investments are building on a legacy of watershed conservation projects already underway in the region funded by ASOCAÑA in collaboration with the grassroots community organizations. The water fund is helping to formalize and expand these prior investments by bringing the water users and providers together in a partnership to ensure joint decision making and scientifically sound investment choices.

The Case of Brazil

In the Atlantic Forest and other biomes of Brazil, TNC and partners have had great success in replicating a similar watershed conservation model called the water producer concept that has now been added to the water fund portfolio of TNC (*see* Water Fund Platform). The water producer concept was first developed by the National Water Agency (ANA) and first implemented by ANA, TNC, and several state and local partners. It recognizes the positive externalities generated by landowners living in the headwaters of watersheds when they implement forest and soil conservation and restoration activities and that people downstream benefit from these positive externalities. The concept is based on the premise that those who benefit should pay directly for that which benefits them, in this case watershed conservation. Thus landowners are compensated for their opportunity costs for generating the hydrologic services downstream users require.

Brazil's Atlantic Forest is the most densely populated region in Latin America as it is home to 11 major cities including Sao Paulo and Rio de Janeiro and 70% of Brazil's population. Since 2006, TNC and partners have been working in the watersheds of the Atlantic Forest that provide 50% of Sao Paulo's drinking water and 80% of Rio de Janeiro's. Brazil holds more water than any nation, but only 1/12 of that water can be found along the southeastern coast where nearly half of the population lives (Bradley, 2010). The forest is also one of the most biodiverse areas on earth, with 5% of the earth's vertebrates and 8% of the planet's plants. Unfortunately, much of the forest is becoming rapidly degraded and only 12% remains. Clearing and fragmentation is the main threat to its viability in the long term.

Deforestation threatens the provision of a clean, reliable water supply and signals an urgent need to protect and restore Brazil's Atlantic Forest. Water producer projects involve direct payments from water users that go toward maintaining and enhancing watershed forest cover. The incentive for water users is sustainable clean, regular water supplies at a lower cost. In Sao Paulo, for example, pollution and sediment in the water have doubled treatment costs in 8 years (Bradley, 2010). Investments in reforestation provide a natural pollution and sediment filtration system that can help curb these costs in the future.

The implementation of water producer projects in Brazil has followed three main routes (Veiga and Gavaldão, 2011). The first one is a result of the National Water Policy that established a water-user fee and required the proceeds to go toward maintaining and increasing watershed health. In addition, it created watershed committees that comprise water users and representatives of governments and civil society and have the legal power to decide the best way to spend the proceeds. The implementation of the policy and the creation of the watershed committees is ongoing gradually throughout Brazil and has started with more urbanized states such as São Paulo, Minas Gerais and Rio de Janeiro where the water-use conflicts are more prominent. The fundraising potential of these watershed schemes is significant. One example is the Piracicaba-Capivari-Jundiaí Watershed (PCJ), one of Brazil's key watersheds, which raises approximately $25 million per year in water user fees.

Creating a water producer project from this policy arrangement involves several steps. The concept is presented to the watershed committees as one of the best investments that the committee could make to guarantee water in quality and quantity from the watersheds in their jurisdiction by explaining that the concept is based on direct payments to compensate watershed landowners for the positive externalities they generate when they restore and protect their lands. The first water producer project created this way began in 2006 in the PCJ Watershed where the watershed committee allocated $250,000 for a first pilot in the watershed matching the funds allocated by a coalition of partners including ANA, the Environmental and Agricultural State Agencies of São Paulo State (SMA-SP and SAA-SP), and TNC (Veiga, 2009). These same partners created a project management unit that manages the pilot and creates plans for its replication within the watershed. Since this first pilot, more initiatives have been replicated in PCJ and other watersheds in the country, including the Guandu Watershed which provides water for the Rio de Janeiro metropolitan area.

A second means by which water producer projects have been created requires municipal and state legal approval explicitly for developing PES schemes. These laws are important for two reasons. They can provide a legal framework for PES implementation, and they can enable and facilitate the use of public funds for PES schemes. For example, one water producer project was based on a 2005 law in Extrema, Minas Gerais, that gave the municipality the ability to pay landowners who achieved specific targets related to soil conservation measures, rural sanitation, and forest conservation and restoration. In addition, this law allowed the first direct payment to a water producer to be made in Brazil in February, 2007. This initiative was a partnership between the municipality, ANA, the State Forestry Agency, and TNC, and support was also received from the PCJ watershed committee. In addition to direct payments for environmental services, the landowners also receive financial, technical, and in-kind support to reach conservation targets. Another example at the state level occurred in 2008 in Espírito Santo where a law was passed that created a water fund called FUNDÁGUA that was primarily funded by a percentage of the oil royalties collected by the state. FUNDÁGUA stipulates that most of the fund's revenues should go toward paying landowners in priority watersheds for the water services they provide. The first payments started in March 2009; by July 2011 approximately 300 landowners received direct payments from FUNDÁGUA.

With these examples, several other municipalities and states have been discussing and implementing laws and PES programs. TNC has been a partner in nearly all of the initiatives, especially those at the state level realizing the great potential these mechanisms have to conserve watersheds throughout the region. At the federal level in Brazil, there is a PES bill proposal under discussion at the National Congress that was informed by these first municipal and state initiatives.

A third means through which a water producer project has been created is more similar to the water funds in other parts of Latin America and has emerged more recently in Brazil. Here a key water user such as a water utility company takes the lead to implement a PES scheme. One example is a project headed by the Balneário Camboriú Municipality Water utility (EMASA), located in one of the most important touristic cities in Southern Brazil. This utility understood the benefits of investing in watershed conservation to reduce its water treatment costs and so has allocated $1.5 million to the PES scheme. Using other water fund projects as examples, the utility and their partners (the municipalities of Camboriú, Balneário Camboriú, ANA, TNC, and the local watershed committee, among others) intend to create a municipal PES water fund to guarantee the initiative's sustainability in the long term. These schemes are also starting to be replicated. For example, SANEATINS, the water utility company of Palmas, the capital of Tocantins state, is now initiating a water fund.

A final, very nascent method for creating a PES scheme similar to a water fund in Brazil involves companies that are trying to offset their water footprints. One mechanism by which they can offset water consumption could be to invest in a water producer project. This possibility is still under development but can be considered another important source of funding for the long term, especially if the project is set up like other water funds in Latin America.

In short, the financial mechanisms in Brazil are slightly different from those of the water funds of the Northern Andes region. In general, however, the funds use an annual distribution model where fees or other sources of funding are collected and distributed each year rather than going into a trust. The payments are direct and are used to both conserve standing forest and to reforest critical areas, and they are generally based on opportunity costs to the farmer from having to reforest and/or protect and/or improve management of their land. Payments tend to range from $29–$100 per acre per year depending on the project site and on institutional arrangements. There are additional criteria that are specific to the sort of scheme proposed such as a landowner's willingness to participate, slope intensity, and forest quality among others that can be combined with opportunity costs. The water fund supplies materials and capacity (hiring local people) to enable reforestation. Restoration costs also vary but are round $1600 to $2800 per acre. The landowner's responsibility is to protect and maintain reforested or forested areas in exchange for a payment based on the location and size of restored and/or conserved parcels.

Water Fund Platform

With all the valuable experience it has gained in developing diverse approaches to watershed conservation through PES schemes, TNC in collaboration with three main partners – IDB, GEF, and FEMSA Foundation, the largest Coca-Cola bottling company in the world – is launching a water fund platform. Using this platform, the characteristics of the water funds in the Northern Andes and the PES approaches in Brazil will be extended to water funds more broadly throughout Latin America, thereby conserving and enhancing valuable freshwater and terrestrial biodiversity while providing important hydrologic services to people.

In the next 5 years TNC and its partners under the Latin American Water Funds Partnership aim to create, implement and capitalize at least 32 water funds (**Figure 1**; **Table 1**). This will comprise investments of over $27 million to protect seven million acres of water sheds in Ecuador, Colombia, Peru, Brazil, Mexico and other countries in the LAC region (Marx, 2011).

The goals of the platform include the following:

- a total of 32 self-sustaining water funds of which 20 are new;
- conservation of more than seven million acres of important ecosystems;
- effective mechanisms for adapting natural ecosystems that supply water to climate change;
- secure access to water supply for more than 50 million people, industries, and rural areas;
- savings in water treatment costs and reduced productivity loss because of water shortages and reductions in energy supply in rural areas and for industries;
- water funds capitalized with at least $27 million (total across all funds) from public and private local funds after 5 years;
- at least $143 million in conservation projects, total across all water funds, on watersheds leveraged from other institutions.

As of December 2011, the platform encompassed 45 water funds in various stages of implementation (**Figure 1**; **Table 1**), most of which were just starting operations or were in the initial stages of assessing feasibility and viability.

Glossary

Mitigation wetland Wetland created, restored, or enhanced to replace lost wetlands.

Wetland Land that is saturated with water long enough to promote wetland or aquatic processes as indicated by poorly drained soils, hydrophytic vegetation, and various kinds of biological activity, which are adapted to a wet environment.

Wetland bank A site where wetlands and/or other aquatic resources are restored, created, enhanced, or in exceptional circumstances, preserved expressly for the purpose of providing compensatory mitigation in advance of authorized impacts to similar resources.

Wetland creation The conversion of a persistent upland or shallow water area into a wetland by human activity.

Wetland restoration The return of a wetland from a disturbed or altered condition caused by human activity to a previously existing condition.

Introduction

Wetlands have been described as "ecological supermarkets" because of the extensive food chain and rich biodiversity that they support (Mitsch and Gosselink, 2007). They play major roles in the landscape by providing unique habitats for a wide variety of flora and fauna. They support a wide variety of plant, and microbial species where the "critters" come from both terrestrial and deepwater aquatic systems to reproduce, find refuge, eat, or be eaten. More recently, wetlands are being described as important water-quality enhancement ecosystems and flood mitigation systems ("natures' kidneys") and carbon sinks and climate stabilizers on a global scale. These ecosystem services of wetlands are now recognized worldwide and have led to wetland conservation, protection laws, regulations, and management plans. Wetlands have become the *cause célèbre* for conservation-minded people and organizations throughout the world, in part, because they have become symptoms of our systematic dismantling of the world's water resources and in part because their disappearance represents an easily recognizable loss of natural areas to economic "progress." But there is optimism by some that wetlands can be created and restored and that the ecosystem services such as biodiversity protection can be thus restored. Loss rates of wetlands around the world and the subsequent recognition of wetland values have stimulated restoration and creation of these systems (Mitsch and Jørgensen, 2004).

Wetland restoration involves returning a wetland to its original or previous wetland state, whereas wetland creation involves conversion of uplands or shallow open-water systems to vegetated wetlands. Wetland restoration and creation can occur for replacement of habitat, for coastal restoration, and for restoration of mined peatlands. Generally, wetland restoration and creation first involve establishment or re-establishment of appropriate natural hydrologic conditions, followed by establishment of appropriate vegetation communities. Although many of these created and restored wetlands have become functional, there have been some cases of "failure" of created or restored wetlands generally caused by a lack of proper hydrology. Creating and restoring wetlands needs to be based on the concept of self-design whereby any number of native propagules can be introduced, but the ecosystem adapts and changes itself according to its physical constraints, and success should not solely be determined by specific plant and animal presence.

Definitions

Wetlands have many distinguishing features, the most notable of which are the presence of standing water for some period during the growing season, unique soil conditions, and organisms, especially vegetation, adapted to or tolerant of saturated soils. Wetlands are unique because of their hydrologic conditions and their role as ecotones between terrestrial and aquatic systems. Terms such as swamp, marsh, fen, and bog have been used in common speech for centuries to define wetlands and are frequently used and misused at present. Formal definitions have been developed by several federal agencies in the US, by scientists in Canada and the US, and through an international treaty known as the Ramsar Convention. These definitions include considerable detail and are used for both scientific and management purposes.

The most common definition of wetlands used in the world is the one developed as part of the Convention on Wetlands of International Importance Especially as Waterfowl Habitat, better known as the Ramsar Convention:

> areas of marsh, fen, peatland or water, whether natural or artificial, permanent or temporary, with water that is static or flowing, fresh, brackish, or salt including areas of marine water, the depth of which at low tide does not exceed 6 m.

This definition, which was adopted at the first meeting of the convention in Ramsar, Iran, in 1971, states that wetlands may incorporate riparian and coastal zones adjacent to the wetlands and islands or bodies of marine water deeper than 6 m at low tide lying within the wetlands. This definition does not include vegetation or soil and extends wetlands to water depths of 6 m or more, well beyond the depth usually

considered wetlands in the US and Canada. The rationale for such a broad definition of wetlands is based on its original intention to include habitats for water birds.

In North America, there are at least five separate word definitions of wetlands (see Mitsch and Gosselink, 2007 for a summary of all). The one that is used to legally protect and define wetlands in the USA is the so-called US Army Corps of Engineering definition:

> The terms "wetlands" means those areas that are inundated or saturated by surface or groundwater at a frequency and duration sufficient to support and that under normal circumstances do support a prevalence of vegetation typically adapted for life in saturated soil conditions. Wetlands generally include swamps, marshes, bogs, and similar areas. (33 CFR 328.3(b); 1984)

Canada has developed a specific national definition of wetlands that may be the best of all:

> land that is saturated with water long enough to promote wetland or aquatic processes as indicated by poorly drained soils, hydrophytic vegetation, and various kinds of biological activity, which are adapted to a wet environment. (Zoltai and Vitt, 1995; Warner and Rubec, 1997)

It is illustrative that the first two definitions above retreat to common terminology used to define wetlands such as "marsh," "fen," "peatland," "swamp," and "bog." **Table 1** lists many of the common terms that are used around the world to define wetlands. These common terms have specific meanings to scientists yet are widely used by the public, often well beyond the generally accepted scientific definitions. In some cases, words such as "swamp" have different meanings in North America and Europe. "Wetland" is a relatively new term in the scientific literature (one of the first uses of it was in a US Fish and Wildlife publication in 1956), but wetland definitions now abound, but there is not one that will prove satisfactory to all users (Mitsch and Gosselink, 2007). Different definitions have been formulated by geologists, soil scientists, hydrologists, botanists, ecologists, economists, political scientists, public health scientists, lawyers, and the public at large. Wetlands are not easily defined, especially for legal purposes, because they have a considerable range of hydrologic conditions, because they are found along a gradient at the margins of well-defined uplands and deepwater systems, and because of their great variation in size, location, and human influence (**Figure 1**). No absolute answer to "What is a wetland?" should be expected, but a combination of the three definitions above is more than sufficient to provide adequate description of wetlands from a structural and functional views.

Global Extent of Wetlands

The extent of the world's wetlands is generally thought to be from 5 to 9 million km^2 or about 4–6% of the land surface of the Earth (**Table 2**). Estimated areas of wetlands in parts of North America are fairly robust with 43.6 million ha in the lower 48 states, 71 million ha in Alaska, and 127 million ha in Canada; these collectively represent about 30% or more of the world's wetlands. The loss of wetlands in the world caused by humans is difficult to determine, but it is probably similar to the 50% loss rate estimated for the lower 48 states of the US, with high rates of loss in Europe and parts of Australia, Canada, and Asia.

Threats to Wetlands

Wetland impacts have included both wetland alteration and wetland destruction. In earlier times, wetland drainage was considered the only policy for managing wetlands in the western world. With over 70% of the world's population living on or near coastlines, coastal wetlands have long been destroyed through a combination of excessive harvesting, hydrologic modification and seawall construction, coastal development, pollution, and other human activities. Likewise, inland wetlands have been continually affected, particularly through hydrologic modification and agricultural and urban development. By 1985, 56–65% of wetlands in North America and Europe, 27% in Asia, 6% in South America, and 2% in Africa had been drained for intensive agriculture. Other human activities such as forestry, stream channelization, aquaculture, dam, dike, and seawall construction, mining, water pollution, and groundwater withdrawal all had impacts, some severe, on wetlands (**Table 3**). Wetlands are degraded and destroyed indirectly as well through alternation of sediment patterns in rivers, hydrologic alternation, highway construction, and land subsidence. Wetlands are also managed close to their natural state for certain objectives such as fish and wildlife enhancement, agricultural and aquaculture production, water-quality improvement, and flood control. Management of wetlands for coastal protection has now taken on more significance.

Wetland Creation and Restoration

The literature on wetland creation and restoration has exploded like no other wetland topic. Mitsch (1994) and Streever (1999) provided early regional overviews and case studies of wetland restoration from around the world. Some general principles and details of techniques are included in the book *Ecological Engineering and Ecosystem Restoration* (Mitsch and Jørgensen, 2004). A critique of the policies and techniques of wetland creation and restoration in the US was published as NRC (2001).

Wetland restoration refers to the return of a wetland from a disturbed or altered condition caused by human activity to a previously existing condition. The wetland may have been degraded or hydrologically altered and restoration then may involve reestablishing hydrologic conditions to re-establish previous vegetation communities. *Wetland creation* refers to the conversion of a persistent upland or shallow water area into a wetland by human activity. *Wetland enhancement* refers to a human activity that increases one or more functions of an existing wetland. One type of created wetland, a *constructed wetland*, refers to a wetland that has been developed for the primary purpose of contaminant or pollution removal from wastewater or runoff. This last type of wetland is also referred to as a *treatment wetland*.

Table 1 Common terms used for various wetland types in the world

Billabong – Australian term for a riparian wetland that is periodically flooded by the adjacent stream or river.
Bog – A peat-accumulating wetland that has no significant inflows or outflows and supports acidophilic mosses, particularly *Sphagnum*.
Bottomland – Lowland along streams and rivers, usually on alluvial floodplains, that is periodically flooded. When forested, it is called a bottomland hardwood forest in the southeastern and eastern US.
Carr – Term used in Europe for forested wetlands characterized by alders (*Alnus*) and willows (*Salix*).
Cumbungi swamp – Cattail (*Typha*) marsh in Australia.
Dambo – A shallow treeless wetland in which water collects in the rainy season; term is used in southern Africa.
Delta – A wetland–river–upland complex located where a river forms distributaries as it merges with the sea; there are also examples of inland deltas such as the Peace–Athabasca Delta in Canada and the Okavango Delta in Botswana.
Fen – A peat-accumulating wetland that receives some drainage from surrounding mineral soil and usually supports marshlike vegetation.
Lagoon – Term frequently used in Europe to denote a deepwater enclosed or partially opened aquatic system, especially in coastal delta regions.
Mangal – Same as mangrove.
Mangrove – Subtropical and tropical coastal ecosystem dominated by halophytic trees, shrubs, and other plants growing in brackish to saline tidal waters. The word ''mangrove'' also refers to the dozens of tree and shrub species that dominate mangrove wetlands.
Marsh – A frequently or continually inundated wetland characterized by emergent herbaceous vegetation adapted to saturated soil conditions. In European terminology, a marsh has a mineral soil substrate and does not accumulate peat. See also Tidal freshwater marsh and salt marsh.
Mire – Synonymous with any peat-accumulating wetland (European definition); from the Norse word ''myrr.'' The Danish and Swedish word for peatland is now ''mose.''
Moor – Synonymous with peatland (European definition). A highmoor is a raised bog; a lowmoor is a peatland in a basin or depression that is not elevated above its perimeter. The primitive sense of the Old Norse root is ''dead'' or barren land.
Muskeg – Large expanse of peatlands or bogs; particularly used in Canada and Alaska.
Oxbow – Abandoned river channel, often developing into a swamp or marsh.
Pakihi – Peatland in southwestern New Zealand dominated by sedges, rushes, ferns, and scattered shrubs. Most pakihi form on terraces or plains of glacial or fluvial outwash origin and are acid and exceedingly infertile.
Peatland – A generic term of any wetland that accumulates partially decayed plant matter (peat).
Playa – An arid- to semiarid-region wetland that has distinct wet and dry seasons. Term used in the southwest US for marshlike ponds similar to potholes, but with a different geologic origin.
Pocosin – Peat-accumulating, nonriparian freshwater wetland, generally dominated by evergreen shrubs and trees and found on the southeastern Coastal Plain of the US. The term comes from the Algonquin for ''swamp on a hill.''
Pothole – Shallow marshlike pond, particularly as found in the Dakotas and central Canadian provinces, the so-called prairie pothole region.
Raupo swamp – Cattail (*Typha*) marsh in New Zealand.
Reedmace swamp – Cattail (*Typha*) marsh in the UK.
Reedswamp – Marsh dominated by *Phragmites* (common reed); term used particularly in Europe.
Riparian ecosystem – Ecosystem with a high water table because of proximity to an aquatic ecosystem, usually a stream or river. Also called bottomland hardwood forest, floodplain forest, bosque, riparian buffer, and streamside vegetation strip.
Salt marsh – A halophytic grassland on alluvial sediments bordering saline water bodies where water level fluctuates either tidally or nontidally.
Sedge meadow – Very shallow wetland dominated by several species of sedges (e.g., *Carex, Scirpus*, and *Cyperus*).
Slough – An elongated swamp or shallow lake system, often adjacent to a river or stream. A slowly flowing shallow swamp or marsh in the southeastern US (e.g., cypress slough). From the Old English word ''sloh'' meaning a watercourse running in a hollow.
Swamp – Wetland dominated by trees or shrubs (US definition). In Europe, forested fens and wetlands dominated by reed grass (*Phragmites*) are also called swamps (see Reedswamp).
Tidal freshwater marsh – Marsh along rivers and estuaries close enough to the coastline to experience significant tides by nonsaline water. Vegetation is often similar to nontidal freshwater marshes.
Turlough – Areas seasonally flooded by karst groundwater with sufficient frequency and duration to produce wetland characteristics. They generally flood in winter and are dry in summer and fill and empty through underground passages. Term is specific for these types of wetlands found mostly in western Ireland.
Vernal pool – Shallow, intermittently flooded wet meadow, generally typical of Mediterranean climate with dry season for most of the summer and fall. Term is now used to indicate wetlands temporarily flooded in the spring throughout the US.
Vleis – Seasonal wetland; term used in southern Africa.
Wad (pl. Wadden) – Unvegetated tidal flat originally referring to the northern Netherlands and northwestern German coastline. Now used throughout the world for coastal areas.
Wet meadow – Grassland with waterlogged soil near the surface but without standing water for most of the year.
Wet prairie – Similar to a marsh but with water levels usually intermediate between a marsh and a wet meadow.

Source: Reproduced from Mitsch WJ and Gosselink JG (2007) *Wetlands*, 4th edn., 582 pp. New York: John Wiley & Sons, Inc.

Significant efforts now focus on the voluntary restoration and creation of wetlands. Part of the interest in wetland creation and restoration stems from the fact that we are losing or have lost much of this valuable habitat. Often interest is less voluntary and more in response to government policies such as ''no net loss'' in the US that require the replacement of wetlands for those unavoidably lost. New Zealand, which has lost 90% of its wetlands, has made major efforts to restore marshes and other wetlands in the Waikato River Basin on North Island and in the vicinity of Christchurch on South Island. In southeastern Australia, restoration of the Murray–Darling watersheds, particularly the riverine

billabongs, has become a major undertaking, while coastal plain wetland restoration and creation are occurring in southwestern Australia. There are concerted efforts to restore mangrove forests in the Mekong Delta of Vietnam, along South American coastlines where shrimp farming has destroyed thousands of hectares of mangroves and around the Indian Ocean to provide tsunami and typhoon protection for coastal areas. Tidal marshes have been created along much of China's eastern coastline, and restoration is now occurring in the Yangtze Delta in Shanghai. Wetland restoration and creation are being proposed or implemented on very large scales to prevent more deterioration of existing wetlands (Everglades in Florida), to mitigate the loss of fisheries (Delaware Bay in Eastern USA), to reduce land loss and provide protection from hurricanes (Mississippi Delta in Louisiana), to stabilize a watershed and provide water-quality improvement (Skjern River, Denmark), and to solve serious cases of overenrichment of coastal waters (Baltic Sea in Scandinavia; Gulf of Mexico in USA).

Mitigating Wetland Habitat Loss

Wetland protection regulations in the US and now elsewhere have led to the practice of requiring that wetlands be created, restored, or enhanced to replace wetlands lost in developments such as highway construction, coastal drainage and filling, or commercial development. This is referred to as the process of "mitigating" the original loss, and these "new" wetlands are often called *mitigation wetlands* or *replacement wetlands*. Replacement wetlands are designed to be at least of the same size as the lost wetlands, but more often a *mitigation ratio* is applied so that more wetlands are created and/or restored than are lost. For example, a mitigation ratio of 2:1 means that 2 ha of wetlands will be restored or created for every hectare of wetland lost to development. Considerable controversy exists, for example, in the US, on the question as to whether wetland loss can be mitigated successfully or if it is essentially impossible (NRC, 2001). Robb (2002) reviewed several years' efforts of mitigating wetland loss in Indiana and suggested, based on failure rates of various wetland types, that there should be the following mitigation ratios: 3.5:1 for forested wetlands; 7.6:1 for wet meadows, 1.2:1 for freshwater marshes, and 1:1 for open-water systems.

Table 3 Human actions that cause direct and indirect wetland losses and degradation in the world

Cause	*Estuaries*	*Floodplains*	*Freshwater marshes*	*Lakes/Littoral zone*	*Peatlands*	*Swamp Forest*
Cause direct wetland losses and degradation						
Agriculture, forestry, mosquito control drainage	xx	xx	xx	x	xx	xx
Stream channelization and dredging; flood control	x		x			
Filling – solid-waste disposal; roads; development	xx	xx	xx	x		
Conversion to aquaculture/mariculture	xx					
Dikes, dams, seawall, levee construction	xx	x	x	x		
Water pollution – urban and agricultural	xx	xx	xx	xx		
Mining of wetlands of peat and other materials	x	x		xx	xx	xx
Groundwater withdrawal		x	xx			
Cause indirect wetland losses and degradation						
Sediment retention by dams and other structures	xx	xx	xx			
Hydrologic alteration by roads, canals, etc.	xx	xx	xx	xx		
Land subsidence due to groundwater, resource extraction, and river alternations	xx	xx	xx			

xx, common and important cause of wetland loss and degradation; x, present but not a major cause of wetland loss and degradation. Blank indicates that effect has not been validated.

Source: Reproduced from Dugan P (1993) *Wetlands in Danger*, 192 pp. London: Reed International Books.

One of the most interesting strategies that the private sector and government agencies have developed to deal with the piecemeal approach to mitigation of wetland loss is the concept of a *mitigation bank*. A mitigation bank is defined as "a site where wetlands and/or other aquatic resources are restored, created, enhanced, or, in exceptional circumstances, preserved expressly for the purpose of providing compensatory mitigation in advance of authorized impacts to similar resources" (*Federal Register*, 28 November 1995, "Federal Guidance for the Establishment, Use, and Operation of Mitigation Banks"). In this approach, wetlands are built in advance of development activities that cause wetland loss, and credits of wetland area can be sold to those who are in need of mitigation for wetland loss. Banks are seen as a way of streamlining the process of mitigating wetland loss and, in many cases, providing a large, fully functional wetland rather than small, questionable wetlands near the site of wetland loss.

Wetland Conservation Programs in Agricultural Lands

Conservation programs are now in place to encourage individual farmers in the US to restore wetlands on their land. Both the Conservation Reserve Program (CRP) and the Wetlands Reserve Program (WRP) under the US Department of Agriculture have led to significant areas of wetlands being restored or protected. CRP guidelines, announced in 1997, give increased emphasis to the enrollment and restoration of *cropped wetlands*, that is, wetlands that produce crops but serve wetland functions when crops are not being grown. The CRP also encourages wetland restoration, particularly through hydrologic restoration. In the CRP, participants voluntarily enter into contracts with the US Department of Agriculture to enroll erosion-prone and other environmentally sensitive land in long-term contracts for 10–15 years. In exchange, participants receive annual rental payments and a payment of up to 50% of the cost of establishing conservation practices. The WRP is another voluntary program established in 1990 and is specific for wetland restoration; it offers landowners the opportunity to protect, restore, and enhance wetlands on their property and provides funds for the farmer to do so.

Forested Wetland Restoration

There is less experience at forested wetland restoration and creation compared to herbaceous marshes, despite the fact that these wetlands have been lost at alarming rates. Forested wetland creation and restoration are different from marsh creation and restoration because forest regeneration takes decades rather than years to complete, and there is more uncertainty about the results. Much riparian forest restoration in the US has centered on the lower Mississippi River alluvial valley, where more than 78,000 ha were reforested by federal agencies over the 10-year period 1988–1997 (King and Keeland, 1999), primarily with bottomland hardwood species and, to a lesser extent, deepwater swamp species. This is a small contribution to the restoration of this alluvial floodplain where 7.2 million ha of bottomland hardwood forest were estimated to have been lost (Hefner and Brown, 1985).

Hydrologic and Water Quality Restoration of Watersheds

Lines often blur between wetlands created and restored for habitat restoration and those restored for water quality and hydrology improvement. In fact most wetlands that are restored or created are done so for both habitat recreation and for other ecosystem services. Four large freshwater wetland restorations around the world are presented as case studies here. One of the largest wetland restoration projects in the world is the Florida Everglades where an attempt is made to restore, at least to some degree, the natural hydrologic conditions in the Everglades that are left (see Case Study 1). Another example of a proposed watershed restoration is a large-scale wetland and riparian forest restoration and

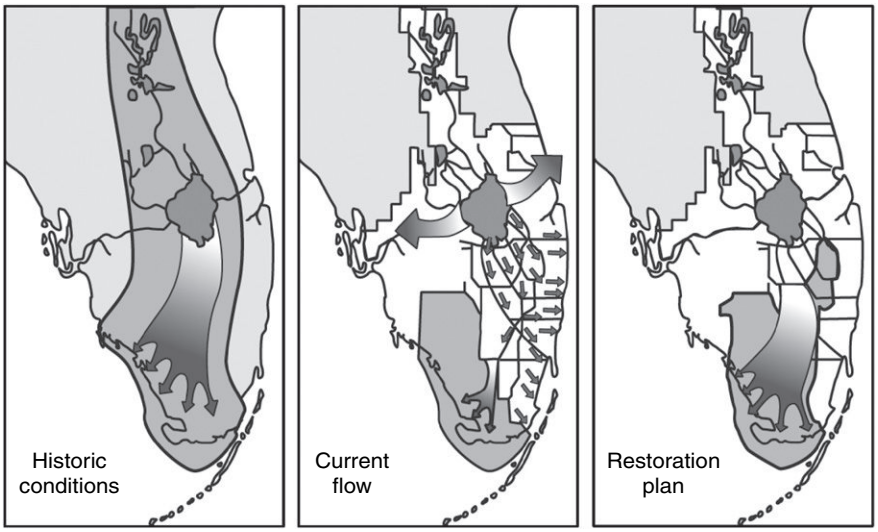

Figure 2 Florida Everglades in historic conditions, current conditions, and planned restoration conditions. Reprinted from Mitsch WJ and Jørgensen SE (2004) *Ecological Engineering and Ecosystem Restoration*, 411 pp. New York: John Wiley & Sons, Inc.

creation, on the order of millions of hectares, being proposed to help solve a major coastal pollution problem in the Gulf of Mexico (see Case Study 2). Restoration done for water quality improvement also has major advantages of also providing habitat restoration and flood mitigation in addition to water quality improvement. The Skjern River Restoration Project in Europe provides a major river/riparian wetland restoration project in a previously drained landscape in Denmark's largest watershed (Case Study 3), while a fourth example of a hydrologic restoration at a culturally significant location in the world that is well underway is the restoration of the Mesopotamian Marshlands of Iraq (Case Study 4).

Case Study 1 – Restoring the Florida Everglades

The restoration of the Florida Everglades, the largest wetland area in the US, actually involves several separate initiatives being carried out in the 4.6 million ha Kissimmee–Okeechobee–Everglades (KOE) region in the southern third of Florida (**Figure 2**). Overall, the Everglades restoration, as now planned by the US Army Corps of Engineers and the South Florida Water Management District, will cost over $12 billion and will be carried out over the next 20 years or more. The basic plan involves restoring something closer to the original hydrology of the KOE region, by sending less of the water from the upper watershed to the Calosahatchee River to the west and the St Lucie Canal to the east (see **Figure 2**, middle diagram) and directing more of the water to the Everglades itself south of Lake Okeechobee (see **Figure 2**, right). Specific problems in the Everglades have developed because of (1) excessive nutrient loading to Lake Okeechobee and to the Everglades itself, primarily from agricultural runoff, (2) loss and fragmentation of habitat caused by urban and agricultural development, (3) spread of *Typha* and other invasives and exotics to the Everglades, replacing native vegetation, and (4) hydrologic alteration due to an extensive canal and straightened rivers system built by the US Army Corps of Engineers and others for flood protection and maintained by several water management districts.

One major restoration project in the KOE region that has received a lot of attention is the restoration of the Kissimmee River. As a result of the channelization of the river in the 1960s, a 166-km-long river was transformed into a 90-km-long, 100-m-wide canal, and the extent of wetlands along the river decreased by 65%. The restoration of the Kissimmee River is a major undertaking to reintroduce the sinuosity to the artificially straightened river. The river restoration work, expected to be completed in stages over the next several decades, will return some portion of lost wetland habitat to the riparian zone and will also provide sinks for nutrients that are otherwise causing increased eutrophication in downstream Lake Okeechobee.

Everglades restoration also involves halting the spread of high-nutrient cattail (*Typha domingensis*) through the low-nutrient sawgrass (*Cladium jamaicense*) communities that presently dominate the Everglades. Since the main causes of the spread of cattails are nutrients and especially phosphorus emanating from agricultural areas in the basin, 16,000 ha of created wetlands, called Stormwater Treatment Areas (STAs) have been created for phosphorus control from the agricultural area (**Figure 3**). A prototype of the STAs, a 1500 ha site, called the Everglades Nutrient Removal (ENR) project has operated since mid-1994 (Reddy *et al.*, 2006).

Case Study 2 – Creating and Restoring Wetlands to Solve the Gulf of Mexico Hypoxia

A hypoxic zone has developed off the shore of Louisiana in the Gulf of Mexico where hypolimnetic waters with dissolved oxygen less than 2 mg l^{-1} O_2 now extend over an area of 1.6–2.0 million ha (Rabalais *et al.*, 2001). Nitrogen, particularly nitrate-nitrogen, is the most probable cause; 80% of the nitrogen input is from the 3 million km^2 Mississippi River basin. The basin represents 41% of lower 48 states of the USA.

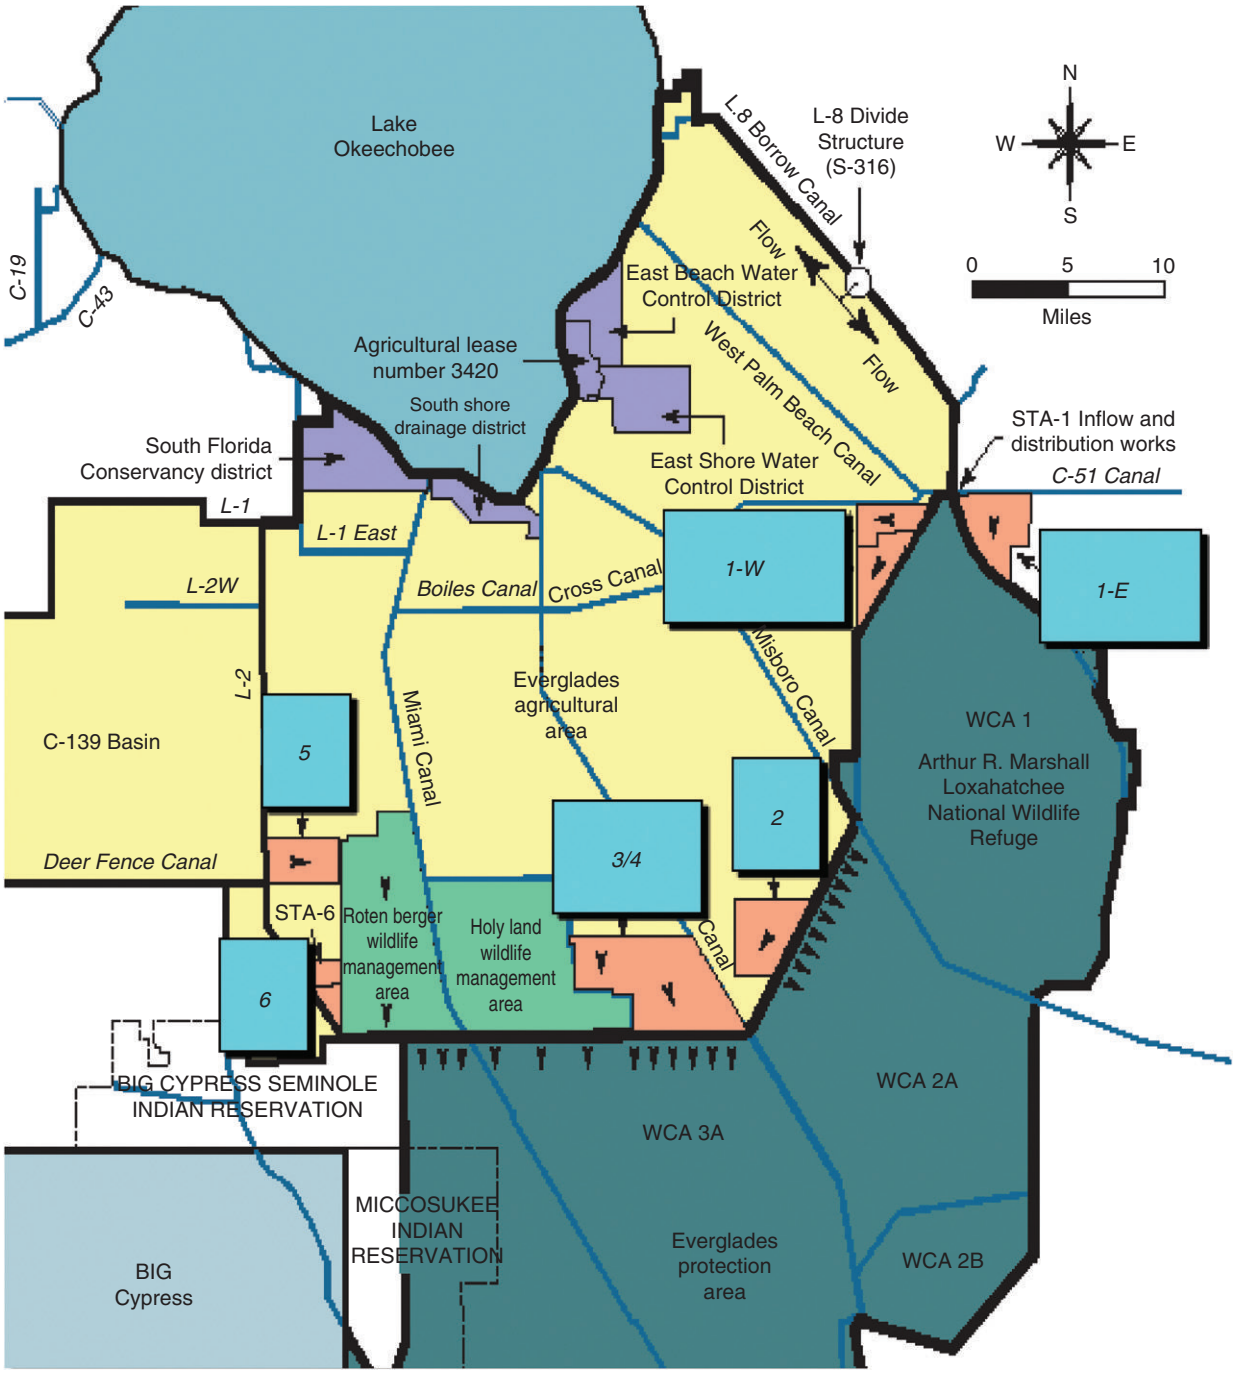

Figure 3 Map of the location of 16,000 ha of Stormwater Treatement Areas (STAs) created north of the Florida Everglades to reduce phosphorus pollution from the Everglades Agricultural Area. Source: South Florida Water Management District, West Palm Beach, Florida.

The control of this hypoxia is important in the Gulf of Mexico because the continental shelf fishery in the Gulf is approximately 25% of the US total. A number of options were investigated for controlling nutrient flow into the Gulf (Mitsch *et al.*, 2001). In the end, there are three general approaches that involve either revision of agronomic approaches or wetland creation and riparian restoration that make the most sense (**Figure 4**). Two million ha of restored and created wetlands and restored riparian buffers have been recommended as necessary to provide enough nitrogen retention to substantially reduce the nitrogen entering the Gulf of Mexico (Mitsch *et al.*, 2001; Mitsch and Day, 2006). That area is less than 1% of the Mississippi River Basin. Interestingly, Hey and Phillipi (1995) found that a similar scale of wetland restoration would be required in the Upper Mississippi River Basin to mitigate the effects of very large and costly floods such as the one that occurred in the summer of 1993 in the Upper Mississippi River Basin.

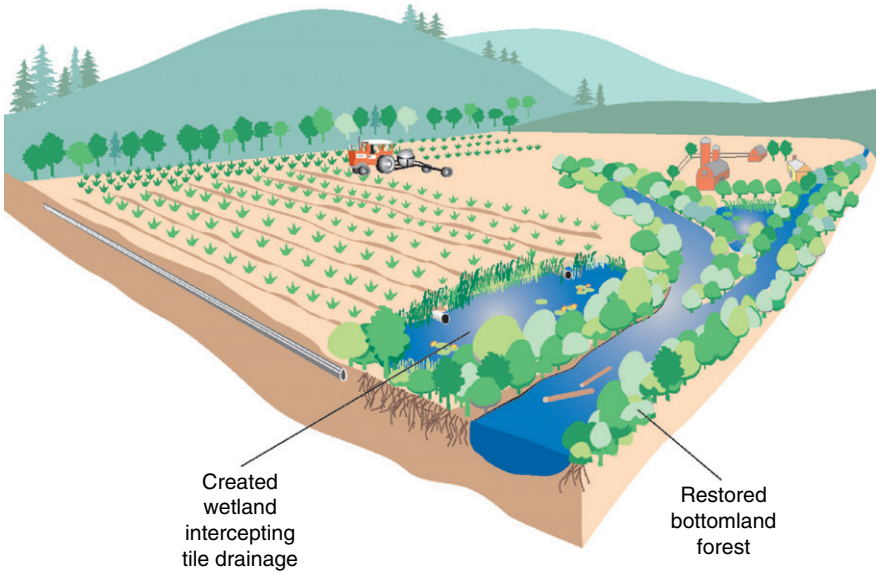

Figure 4 Schematic of agricultural landscape in Mississippi River Basin with wetlands and riparian zones for controlling nitrogen pollution from agricultural fields. Reprinted from Mitsch WJ and Gosselink JG (2007) *Wetlands*, 4th edn., 582 pp. New York: John Wiley & Sons, Inc.

Case Study 3 – The Skjern River Restoration Project, Denmark

River restoration has flourished since the early 1990s in Denmark. The Skjern River in west central Jutland drains more than 11% of Jutland, and the flow of water in the Skjern is the largest in Denmark. In Denmark's largest drainage project ever, 4000 ha of wet meadow was converted into arable land, and the lower Skjern was straightened to a fraction of its former meandering self. By the late 1980s, the river was essentially a straight line to the Ringkobing Fjord on the North Sea, eliminating thousands of hectares of marshland, meadows, and river habitat. The channelized river was diked, canals were built, and pumps were installed to hasten the downstream movement of water from the land. This public works project cost DDK 30 million (about US$3.6 million) and was considered a success by the agricultural community at first as grains could now be grown in the formerly wet region. But the environment was paying a heavy price with this artificial river. The self-cleansing ability of the river was lessened, the downstream fjord was becoming polluted with nutrients and sediments, and the land that was draining began to subside due to peat oxidation and loss of water – up to 1 m or more in some locations. A few years after the drainage, it appeared that another drainage project might be necessary, but the Danish Parliament (Folketing) passed a Public Works Act in 1998 with a huge majority that called for the restoration of the lower Skjern River and earmarked about DDK 254 million for this project. The project is being implemented in three phases for three reaches of the river. Nineteen kilometers of the river and 2200 ha of the river valley wetlands were restored over 1998–2002 (**Figure 5**) by putting back the meanders of the river wherever possible, removing dikes along the river to allow adjacent meadows to once again be flooded, and moving the dikes far away from the river to prevent flooding of farmland outside of the project area. The project was successful in substantially increasing the biodiversity of the region with aquatic macrophytes, invertebrates, amphibians, and mammals such as otters (Pedersen *et al.*, 2007).

Case Study 4 – Restoration of the Mesopotamian Marshlands

The Mesopotamian Marshlands of southern Iraq and Iran, found at the confluence of the historic Tigris and Euphrates Rivers, were 15,000–20,000 km^2 in area as recently as the early 1970s but were drained and diked, especially in the 1990s, to less than 10% of that extent by 2000. Among the main causes are upstream dams and drainage systems constructed in the 1980s and 1990s that altered the river flows and eliminated the flood pulses that sustained the wetlands. Since the overthrow of Saddam Hussein's dictatorship in 2003 in Iraq, there has been a concerted effort by the Iraqis and the international community at restoring the marshlands (Richardson *et al.*, 2005). The restoration has often occurred with local residents breaking dikes or removing impediments to flooding. Remote sensing images showed that at least 37% of the wetlands were restored by 2005, and *Frontiers in Ecology and the Environment* (Vol. 3, No. 8, October 2005) reported that year "at least 74 species of migratory waterfowl and many endemic birds have been sighted in a survey of Iraq's marshland… ." It was also reported that as many as 90,000 Marsh Arabs have returned to the wetlands already (Azzam Alwash, personal communication, 2006). Alwash, the Director of the Eden Again effort, has suggested that perhaps as much as 75% of the marshlands will be restored. There are still several questions that remain unanswered about whether full restoration can occur, including whether adequate water supplies exist given the competition from Turkey, Syria, and Iran, and within Iraq itself, and whether landscape connectivity of the marshes can be re-established (Richardson and Hussain, 2006).

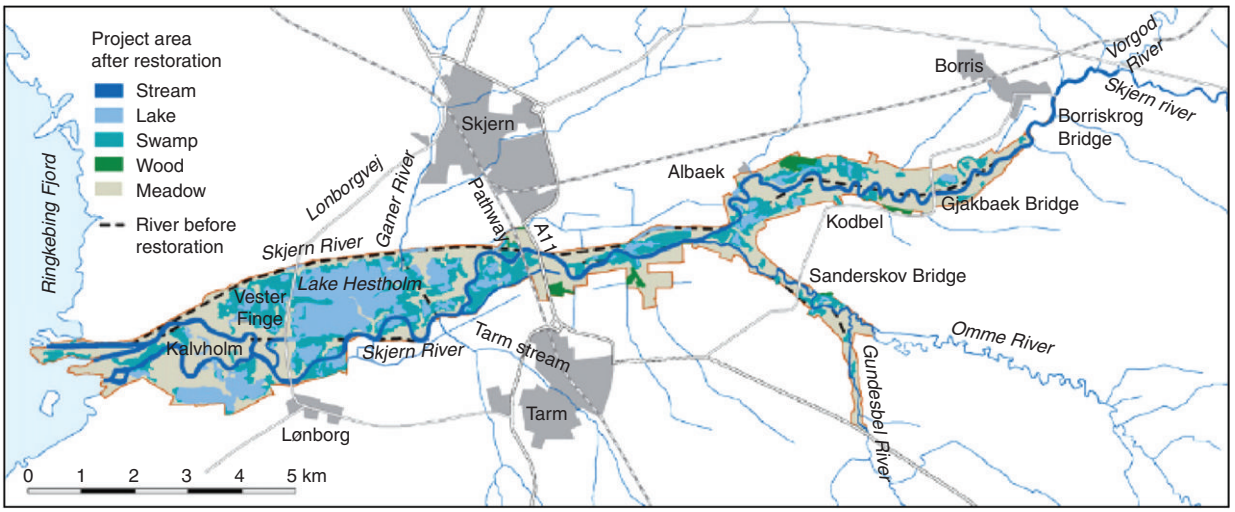

Figure 5 Skjern River restoration area in western Denmark illustrating restoration and floodplain (meadow, lake, and swamp) restoration and river before restoration. Reproduced from Pedersen ML, Andersen JM, Nielsen K, and Linnemann M (2007) Restoration of the Skjern River and its valley: Project description and general ecological changes in the project area. *Ecological Engineering* 30: 131–144.

Peatland Restoration

Peatland restoration is a relatively new type of wetland restoration compared to other types and potentially could be the most difficult (Gorham and Rochefort, 2003). Early attempts with peatlands occurred in Europe, specifically in Finland, Germany, UK, and The Netherlands. Increased peat mining in Canada and elsewhere has led to increased interest in understanding if and how mined peatlands can be restored. When peat surface mines are abandoned without restoration, the area rarely returns through secondary succession to the original moss-dominated system (Quinty and Rochefort, 1997). There is promise that restoration can be successful but because (1) surface mining causes major changes in local hydrology and (2) peat accumulates at an exceedingly slow rate, restoration progress will be measured in decades rather than years. In the 1960s and 1970s, block harvesting of peat was replaced by vacuum harvesting in southern Quebec and in New Brunswick, necessitating the development of different restoration techniques. While traditional block-cutting of peat left a variable landscape of high ground and trenches, vacuum harvesting left relatively flat surfaces bordered by drainage ditches. Abandoned block-cut sites appear to revegetate with peatland species more easily than do vacuum-harvested sites, and the latter can remain bare for a decade or more after mining (Rochefort and Campeau, 1997).

Case Study 5 – Bois-des-Bel Peatland, Québec, Canada

Despite the vast expanses of peatlands in the world, whole-ecosystem experiments on this type of wetland are rare. Bois-des-Bel peatland, located about 200 km northeast of Québec City, on the southern shore of the St Lawrence River in Québec, Canada, is a whole-ecosystem research site where scientists are evaluating the pace of peatland restoration after peat mining (Rochefort *et al.*, 2003). The entire peatland is about 210 ha; the research area is about 11.5 ha of peatland that was drained in 1972 and mined by a vacuum extraction technique from 1973 to 1980. When mining stopped, a 2-m peat deposit remained. Restoration began in 1999 on 8.4 ha of the site, with the remaining as an unrestored control. The restored area was divided into four zones, each of which has two shallow pools (13 m × 5 m × 1.5 m max depth) for aquatic and amphibian habitat. Line Rochefort and her students and colleagues at Université Laval, Quebec City, and at other Canadian universities have established the site as a long-term ecosystem research site here to investigate the revegetation of mined peatlands (Price *et al.*, 1998; Rochefort *et al.*, 2003; Waddington *et al.*, 2003, 2008; Isselin-Nondedeu *et al.*, 2007). The restoration involved terracing to produce better water distribution, reintroduction of *Sphagnum* diaspores harvested from a nearby natural wetland, and reflooding by blocking drainage ditches. The moss carpet increased by about 12 cm by 2007 and was three times the thickness that it was in 2003. *Sphagnum* cover by 2005 was 60% of the area in the restored sites compared to only 0.25% in the nonrestored sites (Isselin-Nondedeu *et al.*, 2007). The restored sites also exported less than half the dissolved organic carbon than did the cutover peatland sites (Waddington *et al.*, 2008).

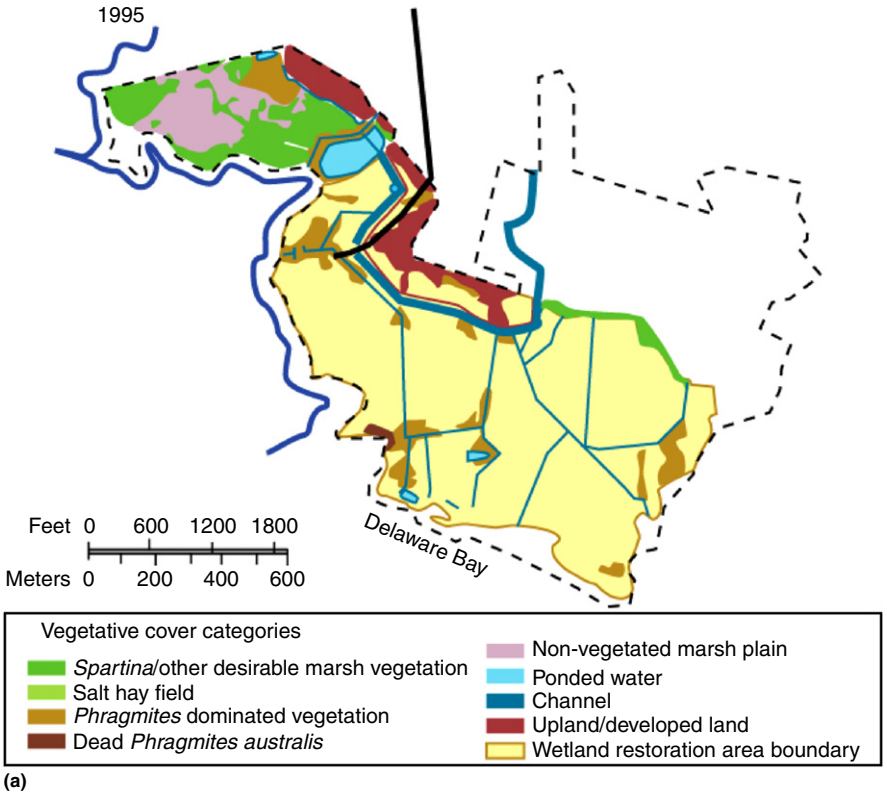
Coastal Wetland Restoration

There is a great deal of interest in coastal wetland restoration. Early pioneering work on salt marsh restoration was done in Europe, China, North Carolina, Chesapeake Bay and Delaware Bay in the USA, and along the coastlines of Florida, Puerto Rico, and California. Some of this coastal wetland restoration has been undertaken for habitat development as mitigation for coastal development projects. For coastal salt marshes in Eastern US, the cordgrass *Spartina alterniflora* is the primary choice for coastal marsh restoration; but the same species is considered an invasive and unwanted plant on the west coast of North America. Both *Spartina townsendii* and *S. anglica* have

been used to restore salt marshes in Europe and in China although both species are considered to be invasive by some in China and New Zealand. Salt marsh grasses tend to distribute easily through seed dispersal, and the spread of these grasses can be quite rapid once the reintroduction has begun, as long as the area being revegetated is intertidal, that is the elevation is between ordinary high tide and low tide.

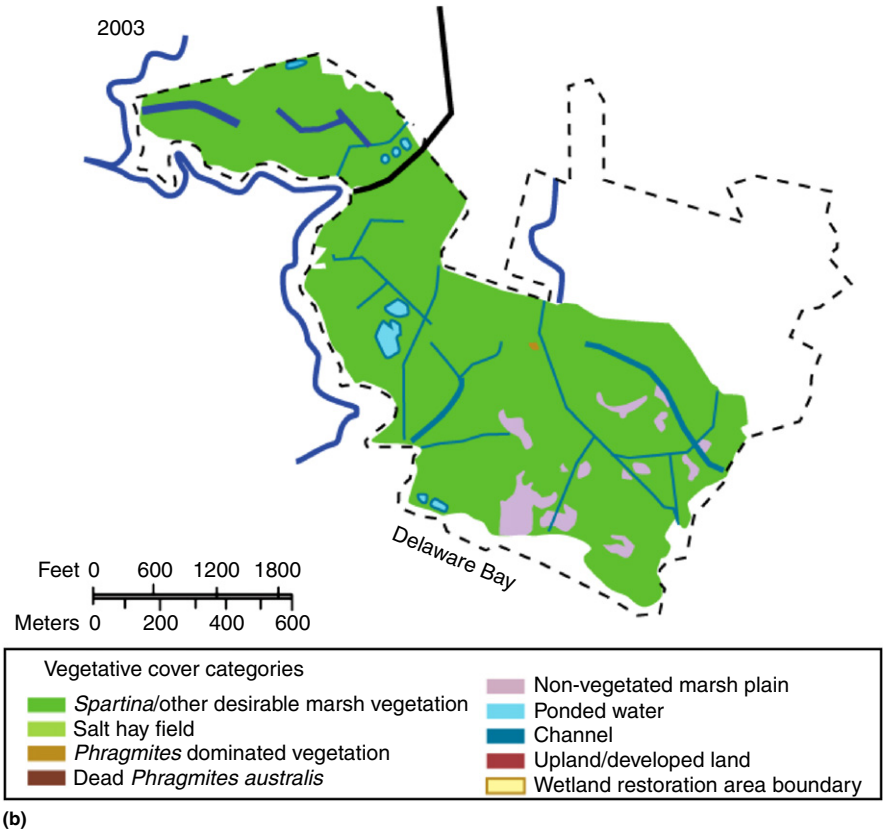
Restoring mangrove swamps in tropical regions of the world has some similar characteristics to restoring salt marshes in that the establishment of vegetation in its proper intertidal zone is the key to success. But that is generally where the similarities end. Mangrove restoration is more cosmopolitan in that it has been attempted throughout the tropical and subtropical world (Lewis, 2005); salt marsh restoration has been attempted primarily on the Eastern North American and Chinese coastlines and to some extent in Europe and the west coast of North America. Salt marsh restoration can often rely on water-borne seeds distributing through an intertidal zone; mangrove restoration often involves the physical planting of trees. In countries such as Vietnam, mangrove declines have been attributed to the spraying of herbicides during the Vietnam war, and immigration of people to the coastal regions, leading to cutting of lumber for timber, fuel, wood, and charcoal.

Mangroves are being cleared for construction of aquaculture ponds at unprecedented rates in Vietnam and many other tropical coastlines of the world (Benthem *et al.*, 1999). Most of the edible shrimp sold in the US and Japan are produced in artificial ponds constructed in mangrove wetlands in Thailand, Indonesia, and Vietnam. These products are the result of massive destruction of mangrove forests and are sold in the US and Japan at very low prices. More than 100,000 ha of abandoned ponds located in former mangrove swamps currently exist in these countries (R. Lewis, personal communication). In Vietnam, mangroves are being restored and protected to provide coastal protection and coastal fisheries support. In the Philippines, despite a presidential proclamation in 1981 prohibiting the cutting of mangroves, it is estimated that the country was still losing 3000 ha yr^{-1} in the late 1990s (2.4% yr^{-1}; de Leon and White, 1999). Shrimp ponds last only about 5–6 years before they develop toxic levels of sulfur and are then abandoned, and more mangroves are destroyed. These abandoned ponds present a challenge for mangrove restoration.



Several studies emphasized the importance of restoring tidal conditions, including salinity, to marsh or mangove areas that had become more "freshwater" because of isolation from the sea. In cases such as this, the restoration is simple – remove whatever impediment is blocking tidal exchange. Case Study 6 describes a salt marsh restoration in Delware Bay where that is exactly the case – restore the natural tidal hydrology, and the vegetation and aquatic species will follow.

Case Study 6 – Delaware Bay Salt Marsh Restoration



A large coastal wetland restoration project in Eastern USA involves the restoration, enhancement, and preservation of 5000 ha of coastal salt marshes on Delaware Bay in New Jersey and Delaware in northeastern USA (Teal and Peterson, 2005). This estuary enhancement, being carried out by New Jersey's electric utility with advice from a team of scientists and consultants, was undertaken as mitigation for the potential impacts of once-through cooling from a nuclear power plant operated on the Bay. The reasoning was that the impact of once-through cooling on fin fish, through entrainment and impingement, could be offset by increased fisheries production from restored salt marshes. Because of uncertainties involved in this kind of ecological trading, the area of restoration was estimated as the salt marshes that would be necessary to compensate for the impacts of the power plant on fin fish times a safety factor of four. There are two distinct approaches being utilized in this project to restore the Delaware Bay salt marshes:

1. Reintroduce flooding: The most important type of restoration involves the reintroduction of tidal inundation to about 1800 ha of former diked salt hay farms. Many marshes along Delaware Bay have been isolated by dikes from the bay, sometimes for centuries, and put into the commercial production of "salt-hay" (*Spartina patens*). Hydrologic restoration was accomplished by excavating breaches in the dikes and, in most cases, connecting these new inlets to a system of recreated tidal creeks and existing canal systems. From a hydrodynamic perspective, in those marshes where tidal exchange was restored, the development of an intricate tidal creek density from the originally constructed tidal creeks has been impressive. The "order" of the stream channels increased from 5 or less to well over 20 from 1996 through 2004. The number of small tributaries increased from "dozens" to "hundreds" at all three salt hay farm sites that were reopened to tidal flushing. Hydrologic design did occur in "self-design" fashion after only initial cuts by construction of the first-order channels.
2. Reduce *Phragmites* domination: In another set of restoration sites in Delaware and New Jersey, restoration involves the reduction in cover of the aggressive and invasive *Phragmites australis* in 2100 ha of nonimpounded coastal wetlands. Alternatives that were investigated include hydrological modifications such as channel excavation, breaching remnant dikes, microtopographic changes, mowing, planting, and herbicide application.

Results of this study were reported in several early journal articles (e.g., Weinstein *et al.*, 1997, 2001; Teal and Weinstein, 2002) and more recently in a journal special issue of 10 papers related to this salt marsh restoration (Peterson *et al.*, 2005). For the salt hay farms that were flooded, typical goals include a high percent cover of desirable vegetation such as *Spartina alterniflora*, a relatively low percent of open water, and the absence of the invasive reed grass *Phragmites australis*. Reestablishment of *Spartina alterniflora* and other favorable vegetation has been rapid and extensive. Approximately 64% of one site was dominated by *Spartina alterniflora* after only two growing seasons and 87% by the fifth year after construction (**Figure 6**). Tidal restoration was completed at a larger site and major revegetation by *Spartina alterniflora* and some *Salicornia* already occurred with 71% of the site showing desirable vegetation after only four growing seasons. The study has

(a)

(b)

Figure 6 Restoration of Dennis Township salt marsh on Delaware Bay, New Jersey, USA, from initial conditions in 1995 to restored salt marsh in 2003. Reproduced from Hinkle R and Mitsch WJ (2005) Salt marsh vegetation recovery at salt hay farm wetland restoration sites on Delaware Bay. *Ecological Engineering* 25: 240–251.

shown that the speed with which restoration takes place is dependent on three main factors: the degree to which the tidal "circulatory system" works its way through the marsh; the size of the site being restored; and the initial presence of *Spartina* and other desirable species. No planting was necessary on these sites as *Spartina* seeds arrive by tidal fluxes; but the design of the sites to allow that tidal connectivity (and hence the importance of appropriate site elevations relative to tides) was critical. Self-design works when the proper conditions for propagule disbursement are provided.

River Delta Restoration

As large rivers connect to the sea, multitributary deltas tend to develop, allowing the river to discharge to the sea in many channels. Many of these rich-soil deltas are among the most important ecological and economic regions of the world, from the ancient Nile delta in Egypt to the modern-day Mississippi River delta in Louisiana. There should be two major ecological resource goals of delta areas: (1) protecting and restoring the functioning of the deltaic ecosystems in the context of a geologically dynamic framework and (2) controlling pollution from entering the downstream lakes, oceans, gulfs, and bays. Delta restoration should have this dual emphasis where possible – ecosystem enhancement of the delta itself and improvement of coastal water-quality downstream. The best strategy for delta restoration when "land building" is a prerequisite (see Louisiana case study below) is to restore the ability of the river to "spread out its sediments" in deltaic form as wide an area as possible, particularly during flood events and by not discouraging (or encouraging and even creating) river distributaries. When river distributaries are not possible on a large scale due to navigation requirements or population locations, then restoring and creating riverine wetlands and constructing river diversions to divert river water to adjacent lands may be the best alternatives to maximize nutrient retention and sediment retention. In some cases, this involves the conversion of agricultural lands back to wetlands; in other cases, the dikes that "protect" wildlife protection ponds or retain rivers in their channels only need to be carefully breached to allow lateral flow of rivers during flood season.

Case Study 7 – Louisiana Delta Restoration

Louisiana is one of the most wetland-rich regions of the world with 36,000 km^2 of marshes, swamps, and shallow lakes. Yet Louisiana is suffering a rate of coastal wetland loss of 6600–10,000 ha yr^{-1} as it converts to open water areas on the coastline, due to natural (land subsidence) and human causes such as river levee construction, oil and gas exploration, urban development, sediment diversion, and possibly climate change. There has been, since the early 1990s, a major interest in reversing this rate of loss and even gaining coastal areas, particularly freshwater marshes and salt marshes, the loss of which are the major symptom of this "land loss." Clearly since the disaster in Louisiana and New Orleans caused by Hurricane Katrina in 2005, there is intense interest in restoring the Louisiana delta. But the enormous cost of reestablishing human settlements and putting back levees that were breeched during the hurricane has led some to doubt if there are enough resources to carry out the needed wetland restoration as well (Costanza *et al.*, 2006). Yet the wetlands are vital to the long-term survival of New Orleans. River diversions are becoming a large part of the delta restoration in Louisiana. The deltaic wetlands in Louisiana cover more than 20,000 km^2 and are critical to building land and wetlands from open water in the delta and may be critical nutrient removal sites for abatement of Gulf hypoxia (see Case Study 2 above). The Caernarvon freshwater diversion is one of the largest of several diversions currently in operation on the Mississippi River in Louisiana. The diversion structure is on the east bank of the river below New Orleans 131 km upstream of the Gulf of Mexico. The structure is a five-box culvert with vertical lift gates with a maximum flow of 226 $m^3 s^{-1}$. Freshwater discharge began in August 1991 and discharge from then until December 1993 averaged 21 $m^3 s^{-1}$; current minimum and maximum flows are 14 and 114 $m^3 s^{-1}$, respectively, with summer flow rates generally near the minimum and winter flow rates 50–80% of the maximum (Lane *et al.*, 1999). The Caernarvon diversion delivers water to the Breton Sound estuary, a 1100 km^2 area of fresh, brackish, and saline wetlands.

Creating and Maintaining the Proper Hydrology

The key to restoring and creating wetlands is to develop appropriate hydrologic conditions. Groundwater inflow is often desired because this offers a more predictable and less seasonal water source. Surface flooding by rivers gives wetlands a seasonal pattern of flooding, but such wetlands can be dry for extended periods in flood-absent periods. Depending on surface, runoff and flow from low-ordered streams can be the least predictable. Often wetlands developed under these conditions are isolated pools and potential mosquito havens for a good part of the growing season; their design should be carefully considered. It is generally considered to be optimum to build wetlands where they used to be and where hydrology is still in place for the wetland to survive. But tile drainage, ditches, and river downcutting have often changed local hydrology from prior conditions. Most biologists have difficulty in estimating hydrologic conditions whereas engineers often overengineer control structures that need substantial maintenance and are not sustainable.

Soils

Often choice of the site of wetland creation and restoration is limited by property ownership. If a choice exists, a wetland that is restored on former wetland (hydric) soils is much preferred over one constructed on upland soils. Hydric soils develop certain color and chemical patterns because they have spent long periods flooded and thus under anaerobic conditions. The soil color is mostly black in mineral hydric soils because iron and manganese minerals have been converted to reduced soluble forms and have leached out of the soil. In most cases, developing wetlands on hydric soils has three advantages:

1. hydric soils indicate that site may still have or can be restored to appropriate hydrology;

2. hydric soils may be a *seedbank* of wetland plants still established in the soil; and
3. hydric soils may have the appropriate soil chemistry for enhancing certain wetland processes. For example, mineral hydric soils generally have higher soil carbon than do mineral nonhydric soils. This soil carbon, in turn, stimulates wetland processes such as denitrification and methane production.

Otherwise, it is possible to create wetlands on upland soils, and in the long run, these soils will develop characteristics typical of hydric soils such as higher carbon content and seed banks.

Natural Succession versus Horticulture

To develop a wetland that will ultimately be a low-maintenance one, natural successional processes need to be allowed to proceed. The best strategy is usually to introduce, by seeding and planting, as many native choices as possible to allow natural processes to sort out the species and communities in a timely fashion. Wetlands created or restored by this approach are called *self-design wetlands*. Providing some help to this selection process, for example, selective weeding, may be necessary in the beginning, but ultimately the system needs to survive with its own successional patterns unless significant labor-intensive management is possible. A somewhat different approach, called *designer wetlands*, occurs when specified plant species are introduced, and the success or failure of those plants are used as indicators of success or failure of that wetland. This is akin to horticulture.

An important general consideration of wetland design is whether plant material is going to be allowed to develop naturally from some initial seeding and planting or whether continuous horticultural selection for desired plants will be imposed. Odum (1987) suggested "in many freshwater wetland sites, it may be an expensive waste of time to plant species which are of high value to wildlife.... It may be wiser to simply accept the establishment of disturbance species as a cheaper although somewhat less attractive solution." Reinartz and Warne (1993) found that the way vegetation is established can affect the diversity and value of the mitigation wetland system. Their study showed that early introduction of a diversity of wetland plants may enhance the long-term diversity of vegetation in created wetlands. The study examined the natural colonization of plants in 11 created wetlands in southeastern Wisconsin. The wetlands under study were small, isolated, depressional wetlands. A 2-year sampling program was conducted for the created wetlands, aged 1–3 years. Colonization was compared to five seeded wetlands where 22 species were introduced. The diversity and richness of plants in the colonized wetlands increased with age, size, and proximity to the nearest wetland source. In the colonized sites, *Typha* spp. comprised 15% of the vegetation for 1-year wetlands, and 55% for 3-year wetlands, with the possibility of monocultures of *Typha* spp. developing over time in colonized wetlands. The seeded wetlands had a high species diversity and richness after two years. *Typha* cover in these sites was lower than in the colonized sites after 2 years.

Case Study 8 – To Plant or Not Plant Created Wetlands

A study where the effects of planting versus not planting have been observed for over 15 years is at two experimental wetlands at the Olentangy River Wetland Research Park in central Ohio (**Figure 7**; Mitsch *et al.*, 1998, 2005, 2012). In essence, both wetlands were different degrees of self-design since there were no expectations as to what the ultimate cover would be, and there was no "gardening" to get to any endpoint. After 3 years, both wetlands were principally dominated by soft-stem bulrush *Schoenoplectus tabernaemontani* (=*Scirpus validus*) and were thought to be similar. Researchers found that both planted and unplanted wetlands converged in most of the 16 ecological indicators (eight biological measures and eight biochemical measures) in those 3 years (Mitsch *et al.*, 1998). After 6 years, however, several communities of vegetation continued to exist in the planted basin, but a highly productive monoculture of *Typha* dominated the unplanted basin (Mitsch *et al.*, 2005).

This study has now completed over 15 years of observations where one full-scale wetland was planted, and an identical wetland remained unplanted. The wetlands showed that there are a few differences in wetland function that persist a decade planting in planted and unplanted (naturally colonizing) wetland basins that could be traced to effects of the initial planting (Mitsch *et al.*, 2012). Some values that we appreciate in wetlands, for example, carbon sequestration and amphibian production, were higher in the naturally colonizing wetland while other values such as macrophyte community diversity were higher in the planted wetland. Planting did have an effect, but whether to plant depends on the original objective of the wetland. If plant diversity is desired, then planting makes sense. If productivity and carbon sequestration are desired, it may be a waste of effort to plant unless there are no sources of plant propagules (seed banks or inflowing rivers, for example). In any regard, there appears to be a lingering long-term effect on ecosystem function caused by planting.

Estimating Success

There are few satisfactory methods available to determine the "success" of a created or restored wetland or even a mitigation wetland created to replace the functions lost with the original wetland (Mitsch and Wilson, 1996). It is clear from the many studies of created and restored wetlands that some cases are successes, while there are still far too many examples of failure of created and restored wetlands to meet expectations. In some cases, expectations were unreasonable, as when endangered species habitat was to be established in a heavily urbanized environment (Malakoff, 1998). In such cases, the original wetland should not have been lost to begin with. Where expectations are ecologically reasonable, there is optimism that wetlands can be created and restored and that wetland function can be replaced. The spotty record to date is due to three factors:

1. little understanding of wetland function by those constructing the wetlands;
2. insufficient time for the wetlands to develop; and
3. a lack or recognition or underestimation of the self-design capacity of nature.

Figure 7 Experimental and other created and restored wetlands at the Olentangy River Wetland Research Park, Columbus, Ohio.

Understanding wetlands enough to be able to create and restore them requires substantial training in plants, soils, wildlife, hydrology, water quality, and engineering. Replacement projects and other restorations involving freshwater marshes need enough time, closer to 15 or 20 years than to 5 years, before success is apparent. Restoration and creation of forested wetlands, coastal wetlands, or peatlands may require even more time. Peatland restoration could take decades or more. And, of course, forested wetland restoration generally takes a lifetime.

Principles for Proper Ecological Engineering of Wetlands

Some general principles of ecological engineering that apply to the creation and restoration of wetlands are outlined below (Mitsch and Jørgensen, 2004):

1. Design the system for minimum maintenance and a general reliance on self-design.
2. Design a system that utilizes natural energies, such as the potential energy of streams as natural subsidies to the system.
3. Design the system with the hydrologic and ecological landscape and climate.
4. Design the system to fulfill multiple goals but identify at least one major objective and several secondary objectives.
5. Give the system time.
6. Design the system for function, not form.
7. Do not overengineer wetland design with rectangular basins, rigid structures and channels, and regular morphology.

Zedler (2000a) had suggested the following additional ecological principles that should be applied to wetland restoration:

1. Landscape context and position are crucial to wetland restoration. See #3 design principle above. Wetlands are always a function of the watershed and ecological setting in which they are placed.
2. Natural habitat types are the appropriate reference systems. This suggests that while we may know how to build ponds, for example, are those the natural habitats of the area, even if they do increase waterfowl?
3. The specific hydrologic regime is crucial to restoring biodiversity and function. See # 2 and 3 design principles. In many cases, such as the Florida Everglades, the restoration is being done in the face of a massive change in the hydrologic character of the landscape.
4. Ecosystem attributes develop at different paces. Give the system time; see # 5 above. Hydrology develops quickly, vegetation over several years, and soils over decades. Yet we are quick to review and criticize created and restored wetlands after a couple of years.
5. Nutrient supply rates affect biodiversity recovery. There are low-nutrient and high-nutrient wetland systems. Low-nutrient wetlands are often more difficult to create or restore. High-nutrient inflows cause wetlands to go for power instead of biodiversity. In other cases, insufficient nutrients were the cause of wetland failure as was the case in southern California salt marshes (Zedler, 2000b).
6. Specific disturbance regimes can increase species richness. This can clearly be the case if we allow the word "disturbance" to include flood pulses, fire, and even tropical storms.
7. Seed banks and dispersal can limit recovery of plant species richness. This is why restoring wetlands with seed banks can be so important. Another solution is to have a hydrologically or biologically "open" system with a multitude of inputs of propagules (plants, animals, and microbes) more likely.
8. Environmental conditions and life history traits must be considered when restoring biodiversity. See our discussion on self-design versus designer wetlands below.
9. Predicting wetland restoration begins with succession theory. Again, design principle # 5 says we need to give the system time. Ecological succession cannot be accelerated without other consequences. This also supports our contention that one must understand wetland science first before attempting to create and restore wetlands.
10. Genotypes influence ecosystem structure and function. This is an important but often overlooked principle of wetland restoration. Species are not the same everywhere. This has been shown in common garden experiments on *Spartina alterniflora* (Seliskar, 1995) and freshwater rush *Juncus effusus* (Weihe and Mitsch, 2000). A brackish/freshwater wetland plant with this several genotypes that has invaded many natural and restored wetlands in the USA is *Phragmites australis*. This creates a difficult problem in wetland creation and restoration as wetland managers must be able to distinguish between the invasive "bad" *Phragmites* and the native "good" *Phragmites*.

Robin Lewis and Kevin Erwin, two wetland consultants from Florida, have spent about five decades restoring and creating wetlands around the world. Their experience has led to the following 15 recommendations (Lewis *et al.*, 1995):

1. Wetland restoration and creation proposals must be viewed with great care, particularly when promises are made to restore or re-create a natural system in exchange for a permit.
2. Multidisciplinary expertise in planning and careful project supervision at all project levels is needed.
3. Clear, site-specific measurable goals should be established.
4. A relatively detailed plan concerning all phases of the project should be prepared in advance to help evaluate the probability of success.
5. Site-specific studies should be carried out in the original system prior to wetland alteration if wetlands are being lost in the project.
6. Careful attention to wetland hydrology is needed in design.
7. Wetlands should, in general, be designed to be self-sustaining systems and persistent features of the landscape.
8. Wetland design should consider relationships of the wetland to the watershed, water sources, other wetlands in the watershed, and adjacent upland and deepwater habitat.

9. Buffers, barriers, and other protective measures are often needed.
10. Restoration should be favored over creation.
11. The capability for monitoring and mid-course corrections is needed.
12. The capability for long-term management is needed for some types of systems.
13. Risks inherent in restoration and creation and the probability of success for restoring or creating particular wetland types and functions should be reflected in standards and criteria for projects and project design.
14. Restoration for artificial or already altered systems requires special treatment.
15. Emphasis on ecological restoration of watersheds and landscape ecosystem management requires advanced planning.

The above principles and practices of wetland creation and restoration are based on wetland science (hydrology, biogeochemistry, adaptations, and succession). If one is interested in creating and restoring wetlands, one should first become an expert in wetland science. When we attempt to create or recreate natural ecosystems, Mother Nature is in control. In all situations of wetland creation and restoration, human contribution to the design of wetlands should be kept simple and should strive to stay within the bounds established by the natural landscape. As stated by Boulé (1988) "simple systems tend to be self-regulating and self-maintaining." We should recognize that Nature remains the chief agent of self-design, ecosystem development, and ecosystem maintenance; humans are not the only participants in these processes. We have referred to these self-design and time requirements for successful ecosystem restoration and creation as invoking "*Mother Nature and Father Time*" (Mitsch and Wilson, 1996; Mitsch *et al.*, 1998, 2012).

Glossary

Benthic Located on the bottom of a water body, or pertaining to bottom-dwelling organisms.
Biological diversity The variety of different forms of life on earth, usually considered to include variety at all levels of biological organization from genetic variation to variety seen in species, populations, communities, and ecosystems.
Bog An acidic peatland that receives all water inputs from the atmosphere and hence has low pH (usually 3.4–4.6), low alkalinity, and negligible concentrations of base cations in surface waters; typically dominated by mosses of the genus *Sphagnum* and other plants able to tolerate low pH and low nutrient availability – that is, members of the heath family (Ericaceae).
Calcareous fen A term variously used for wetlands with high calcium carbonate in water and soils. In the strict sense, the term refers to peat-accumulating wetlands with surficial deposits of calcium carbonate and a distinctive flora of calciphilic species. These wetlands typically develop where substantial amounts of cold, calcium-carbonate rich groundwater discharge to the surface.
Detritivores Organisms that consume dead plant or animal material.
Emergent vegetation Rooted plants that tolerate saturated or flooded soil but not extended periods of submersion.
Floodplain Broad, flat areas adjacent to rivers and streams that become inundated during floods.
Hydrologic regime The aggregate set of variables describing the behavior of water in wetlands, including water depth, magnitude and frequency of water level fluctuations, seasonal pattern of water fluctuations, direction and velocity of water flows, and water residence time.
Hydrophytes Plants capable of growing and persisting in saturated or flooded soils.
Littoral The shoreline zone where sunlight penetrates to a wetland's substrate and supports rooted plant growth.
Macroinvertebrates Organisms lacking backbones and generally visible to the human eye.
Marsh A wetland dominated by herbaceous species of plants (e.g., cattails, sedges, grasses, floating ferns) and typically occurring on mineral soils. Floating-leaved and submerged species of plants dominate the parts of marshes that grade into open water. Although the surface layer of some marsh soils may consist of shallow accumulations of organic matter over mineral soils, the depth of this layer is usually less than the minimum required for the site to be classified as peatland.
Peat A type of soil formed from accumulation of the remains of dead plants, with high organic matter content (minimally 20% and as high as 90% by dry weight) and depth greater than 30 to 40 cm. Peat forms in some wetlands because anoxic conditions, low pH, low temperatures and short growing seasons, or plant tissues highly resistant to decay prevent rates of decomposition from keeping up with rates of organic matter production.
Peatlands Wetlands in which dead organic matter accumulates to form peat more than 30 to 40 cm deep; typically includes bogs, poor fens, and rich fens but some swamps also occur on peat.
Poor fen An acidic peatland similar to a bog but having a somewhat higher surface water pH (4.3–5.8) because it receives some groundwater or surface water in addition to precipitation; typically dominated by *Sphagnum* mosses or sedges. But for the presence of distinctive poor-fen indicators, vegetation may superficially resemble bog vegetation or sedge-dominated rich fens that lack *Sphagnum*.
Rich fen An alkaline peatland that receives significant inputs from groundwater or surface water; typically having surface water pHs >6.0, higher alkalinity, and distinctly higher concentrations of base cations than bogs and poor fens; dominated by brown mosses (true mosses, largely of the Amblystegiaceae) and small sedges.
Species richness The number of different species in a specified area.
Submerged vegetation Plants that grow and reproduce while completely submerged.
Swamp Wetlands dominated by woody species. Although the term has been variously used, it is used here in the restricted sense of forested wetland, either on mineral soils or peat. However, while many peatland ecologists classify forested fens on deep peat as swamps, they would not call a bog forest a swamp.

Diversity of Wetland Ecosystems

Wetlands, and the organisms adapted to these unique environments, are as diverse as the myriad combinations of climate, topography, and geology that cause different types of wetlands to form. By definition, wetlands are ecosystems whose physical, chemical, and biological characteristics are determined by the constant or recurrent presence of water at

 http://dx.doi.org/10.1016/B978-0-12-384719-5.00314-2

or near the soil surface. Beyond this commonality, however, lies a seemingly infinite number of ways in which climate and landscape features combine to create wetlands with different: magnitudes and seasonal patterns of water level fluctuation, paths and rates of water movement, soils, water chemistry, nutrient status, and species composition. Out of this landscape diversity rises the large number of different types of wetland ecosystems seen worldwide.

Wetlands occur on every continent except Antarctica and in every climatic regime. The best available estimates indicate that they cover only between 4 and 6% of the Earth's land surface. Within this relatively small area, however, an astonishingly high number of different wetland ecosystem types occur. A recent global summary (Mitsch, 1994) hints at this diversity when it describes the world's wetlands in terms of coarse-scaled differences in climatic setting, geomorphologic setting, and major wetland type. According to that summary, wetlands "are found (a) in humid, cool regions as bogs, fens, and tundra; (b) along rivers and streams as riparian wetlands, seasonally flooded forests, and back swamps; (c) in the delta's of the world's great rivers; (d) along temperate, subtropical, and tropical coastlines as salt marshes, mudflats, and mangrove swamps; and (e) in arid regions as inland salt flats, seasonal playas, and vernal pools". They also are found as (f) marshes, wet meadows, and swamps in depressions that occur in a variety of landscapes and climatic settings; (g) marshes, wet meadows, and swamps on extensive flat areas where the land surface slope is minimal and climate is humid; and (h) marshes, bogs, and fens along the shores of lakes in many climatic regions. Wetlands even occur on (i) slopes as blanket bogs, seepage fens, and vegetated springs.

Finer-scaled differences in climate, geomorphologic setting, and biogeographic region yield an even greater diversity of wetland ecosystem types. Mangrove swamps, for instance, do not exhibit uniform species composition worldwide. The mangrove ecosystems of the Indo-western Pacific have a far greater number of plant species than do the mangrove swamps of Central America, and they certainly should be considered different ecosystems for conservation purposes. The nutrient-poor sawgrass (*Cladium jamaicense*) marshes of the Everglades differ profoundly from the nutrient-rich giant reed grass (*Phragmites australis*) marshes of the Camargue in France's Rhone delta in land form, water chemistry, vegetation, and animal life. Neither of these marsh ecosystems bears much similarity to the thousands of small marshes that dot the prairie pothole region of Canada and the north central United States. The montane cushion-plant herbaceous bogs of Chile contain flora and fauna quite distinct from that of the *Sphagnum* moss-dominated bogs of the Northern Hemisphere, and from the domed bogs of Sarawak. The shore pine (*Pinus contorta*) bogs of Vancouver Island's Pacific coast contain many plant species not seen in Canada's continental bogs. Seasonally flooded forests along rivers include ecosystems as dissimilar as the sometimes monotypic palm swamps of South America, the moderately species-rich hardwood swamps of the southeastern United States (**Figure 1**), and the highly species-rich *varzea* forests of the Amazon basin. Forested wetlands (**Figure 2**) also include those occurring on steep windward slopes of Puerto Rico's Luquillo Mountains where annual precipitation as high as 5000 mm keeps the clayey soils continuously saturated. In Finland, where about one-third of the land is peatland, at least 30 different mire types are recognized. Some of the bogs and fens of Ireland and Scotland, Scandinavia, Finland, Alaska and Canada, the former Soviet Union, and Maine form intricately patterned peatlands, some of the most unique land forms on earth.

Figure 2 Forested wetland in upstate New York, USA.

Classification of the Major Wetland Ecosystems of the World

Because wetlands take so many forms, occur in many different physiographic and climatic settings, and form part of the history and culture of many regions of the world, their diversity is not easily cataloged. Different regional and colloquial names for them abound, as do formal classification systems. Different common names may refer to the same type of wetland with similar species, while the same name may be applied in different parts of the world to wetlands with quite different species. For example, the terms mire, moor, muskeg, and peatland all refer to similar types of wetlands with similar plant growth forms and many common species. On the other hand, the term swamp is used for a variety of forested wetlands in the United States but for areas dominated by giant

reed grass (*Phragmites*) and other herbaceous species in parts of Europe and Africa. Fens dominated by woody species may be called swamps, forested fens, or forested wetlands. In the strictest sense, bogs are peat-accumulating wetlands that receive water only from precipitation. However, the term also is applied to poor fens, which superficially resemble true bogs, and more loosely to any wet vegetated environment that offers less than firm footing.

Numerous formal classifications of the different types of wetlands have been developed. They give some indication of the vast diversity of wetland ecosystems but cannot be used to enumerate that diversity. Because they have been developed for different purposes and from different scientific perspectives, they vary in the criteria used for classification and in the level of resolution to which they classify wetlands. Nonetheless, the existence of literally dozens of wetland classifications worldwide implies the existence of such a high diversity of types that they must be grouped into similar classes for practical reasons of inventory, mapping, management, and scientific communication.

The high diversity of wetland ecosystems also is revealed by considering the many different bases for wetland classification: geomorphologic setting in the landscape, genesis (how they formed), shape or form (e.g., surface morphology, basin morphometry, morphology of the underlying mineral terrain), hydrology (e.g., flooding frequency and duration), sources of water supply, physiognomy of the vegetation, species composition of the vegetation, soil type, water chemistry, and various combinations of these factors. Given that each of these variables represents not a single factor but rather a continuum, the extremely large number of possible combinations becomes apparent. Thus, most classifications in wide use today are broadly based, interdisciplinary, and hierarchical (i.e., consisting of several nested levels with increasing detail only at lower levels in the hierarchy). Species composition, the basis for diversity within wetlands and the focus of many older classifications, is usually not a defining characteristic except at the lowest levels in current classifications. Rather, similarities in hydrology and geomorphology are more likely to form the highest levels of classification, reflecting the importance of the interaction of water with the landscape in determining the biotic characteristics of wetlands.

Nonetheless, the terms bog, fen, marsh, and swamp persist in both scientific and popular literature because of their long history of use and the powerful images they evoke. These terms are not distinguished primarily on the basis of geomorphology or hydrology; nor are they distinguished on any single criterion, nor used consistently. Perhaps the key distinction among them in terms of species diversity is their source or sources of water, which determine hydrologic regime and water chemistry. Greater surface water inputs generally lead to greater water level fluctuations and higher concentrations of base cations and nutrients in marshes and swamps on mineral soils than in bogs and fens. In this chapter, these terms follow current American usage (*see* Glossary).

The current classification systems used in the United States (Cowardin *et al.*, 1979) and Canada (National Wetlands Working Group, 1997) reveal much about the diversity of wetlands in these two countries. For example, the U.S. classification is hierarchical, recognizing 5 major wetland *systems* and 10 *subsystems*, each of which is divided further into 4 to 8 *classes*. A *system* is defined as "a complex of wetlands and deepwater habitats that share the influence of similar hydrologic, geomorphologic, chemical, or biological factors" (Cowardin *et al.*, 1979, p. 4). The five systems are the marine, estuarine, riverine, lacustrine, and palustrine. The term *class* "describes the general appearance of the habitat in terms of either the dominant life forms of the vegetation or the physiography and composition of the substrate—features that can be recognized without the aid of detailed environmental measurements." Classes can be further divided into *dominance* types based on dominant plant species for vegetated sites or on the dominant sedentary or sessile animal species where vegetation is not the dominant cover. Special *modifiers* are used for water regime (type and duration of flooding), water chemistry, soils, and human alterations (e.g., excavated, impounded, diked). Fifty-five classes emerge before one ever gets to the level of dominant species, water regime, or water chemistry.

Most of Canada's wetlands fall within just one system (palustrine) of the U.S. classification. Canada's classification differentiates many types of palustrine wetland, especially peatlands. This classification also is hierarchical but with just three levels: *class, form,* and *type.* Five *classes* are recognized: bog, fen, marsh, swamp, and shallow water. *Forms* are defined on the basis of surface morphology of the wetland, position in the landscape, morphology of the underlying terrain, tidal effects, and proximity to surface water bodies. The Canadian system recognizes 16 bog forms and 4 subforms, 12 fen forms and 7 subforms, 8 marsh forms with 18 subforms, 8 swamp forms with 19 subforms, and 5 shallow water forms with 24 subforms. The 18 *types* based on the general physiognomy of the vegetation (e.g., hardwood treed, coniferous treed, low shrub) modify these 121 forms and subforms. Differences in species composition are left to individual users.

Only the wetlands of western Europe are as well documented as those of the United States and Canada. Specific sites on other continents have received considerable attention but, with few exceptions, comparative regional treatments began to emerge in the English language only 15 years ago, with most appearing since 1990 (*see* References). The exceptions include Chapman's books—for example, *Salt Marshes and Salt Deserts of the World* (1960), *Mangrove Vegetation* (1976), *and Wet Coastal Ecosystems* (1977). However, despite the general lack of scientific studies in many areas of the world, as of 1991, 62 countries from all continents had signed the Convention on Wetlands of International Importance Especially as Waterfowl Habitat (Ramsar Convention) and had designated 527 sites covering more than 30 million ha as being of international importance. Five international wetland symposia have been organized since 1980 by INTECOL (The International Society of Ecology), with a sixth planned for the year 2000 in Quebec City.

Major Regional Wetland Ecosystems

Efforts to classify wetlands into unique entities often obscure, either spatially or temporally, critical connections among parts of what might be viewed as integrated ecological systems.

For example, various classification systems segment the great delta of the Mississippi and Atchafalaya rivers into many types of floodplain forest, freshwater marsh, salt marsh, streams, and lakes. They assign each prairie pothole in the prairie region of the United States and Canada to one of about 20 classes of prairie wetlands. The mangrove forests of Central America are made to seem distinct from the adjacent beds of sea grasses. Functionally, however, these diverse wetlands are linked and might be better viewed as major regional wetland ecosystems. Water, sediments, plant propagules, fish, birds, other animals, genetic material, and pollutants move among them. One type changes through time to become another. Diversity emerges in both space and time from the components as well as their interconnectedness.

In fact, prior to human modification of them, most wetlands existed as complexes of several different types functioning as integrated systems linked by movements of water, sediment, nutrients, plants, and animals. The vast rain-fed and riverine floodplains that form the Sudd in southern Sudan, for example, consist of a complex and dynamic mix of different types of grassland (e.g., *Echinochloa pyramidalis* or *Hyparrhenia rufa* dominated), wild rice marshes (*Oryza longistaminata*), woodlands (*Acacia seyal* or *Balanites aegyptiaca* dominated), and open water that cover more than 45,000 km^2. The great floodplain of the Orinoco River and its tributaries form a nearly 10-million ha wetland complex of streams, ponds, shallow oxbow lakes, riverine forest, marshes, and seasonally-flooded palm (*Copernicia tectorum*) savannas and grassland in Venezuela and eastern Columbia. The eastern shore of Lake Ontario, New York, is bordered by a 17-mile long interconnected system of streams, shallow ponds, marshes, fens, and shrub swamps. Most temperate zone estuaries include freshwater, brackish, and saltwater marshes along with tidal creeks and mudflats. Mangrove swamps, saline lagoons, sea grass beds, and coral reefs form interconnected systems along shallow coasts in subtropical and tropical regions.

These complexes, or assemblages of wetlands within regions, represent another level of wetland diversity that only partially remains today. Current classification systems do not capture such regional ecosystems, though clearly they exist. Many people recognize wetland complexes such as the Everglades and the Prairie Pothole Region as regional ecosystems. Classification systems, however, only recognize hierarchy in types, not in assemblages of wetlands within regions. Current efforts by conservation organizations and government agencies to move to ecoregional mapping attempt to overcome this limitation.

Continental and Regional Diversity

Climate and geomorphology, along with biogeographic factors, control the diversity of wetlands on different continents and in different regions. Wetland development is promoted where precipitation annually exceeds evapotranspiration on a long-term basis. In such climates, wetlands develop in a number of landscape settings, including depressions in the land surface, areas where minimal land surface slope slows surface water runoff, along breaks in the slope of the land surface, and even on slopes if precipitation greatly exceeds evapotranspiration. In semiarid, arid, and desert climates, wetlands occur far less frequently, but they are found (a) in areas with depressions or lowlying land along rivers or coasts where runoff converges from extensive uplands or mountains, (b) along coasts regularly inundated by tides, (c) in areas where permafrost or other impermeable layers below ground prevent or slow infiltration of surface water, and (d) in spring-fed oases.

In addition to topographic variation, variation in the composition and stratigraphy of surficial geological deposits promotes diversity in the types of wetland that occur within a region. The composition of subsurface materials plays a major role in determining the chemistry of water entering wetlands, and thereby the plant species composition of wetlands. For example, wetlands occurring in regions dominated by limestone deposits tend to have high-pH waters rich in base cations that promote the growth of distinctive rich fen vegetation. In contrast, waters draining areas with granitic bedrock tend to be low in pH and base cations; such areas more frequently contain bog-like vegetation. Areas with thick deposits of glacial till can contain a mix of rock types that, in turn, may support a variety of wetland types. A diversity of types in a given region also is promoted where surface topography and subsurface stratigraphy of geological deposits produce groundwater flow paths of varying lengths. Wetland water chemistry is strongly influenced not only by water source but also by the length of groundwater flow paths that enter the wetland and the number of different groundwater flow systems that feed the wetland. Different flow systems may contribute water with different chemistry because the water originates from different geological deposits. If the water originates from the same geological materials, longer flow paths may yield higher concentrations of solutes because longer flow paths generally correlate with longer groundwater residence time (i.e., longer contact time with geological materials).

Biogeographic factors also influence the number of wetland types occurring in different regions and continents. Aquatic plants generally are known for their remarkably wide geographic range, but many species have smaller ranges determined in part by biogeographic factors (i.e., the climatological, geological, glacial, and floristic history of a region). The distributions of these more restricted species help define distinctive biogeographic regions that contain wetlands with species compositions unlike those from other biogeographic regions. For example, shallow ponds that support many species of the Atlantic Coastal Plain flora might be classed broadly as emergent marshes, but this would miss their unique contribution to the diversity of North American wetlands. The flora of these coastal plain ponds, which has an unusual abundance of rare and uncommon species, bears little resemblance to the emergent marshes of other biogeographic regions.

While no systematic comparison has been made of wetland ecosystem diversity in different regions, the factors controlling regional wetland diversity are understood. All other things being equal, regions with the greatest climatic and geomorphologic variation are likely also to contain the highest diversity of wetland types. If wetland types are defined to the level of plant species composition, then biogeography enters into the equation. Thus, continental diversity will vary as a

function of the number and combination of different climatic, geomorphologic, and biogeographic regions occurring on that continent.

Diversity Within Wetland Ecosystems

Plant Species Richness within Wetlands

At the regional and global scale, wetlands clearly exhibit high diversity of types and an associated high diversity of plant species. Within-habitat (or *alpha*) diversity, and between-habitat (or *beta*) diversity, however, is highly variable among wetlands. Wetlands include some of the most species-rich plant communities in the world, as well as numerous examples of extensive stands dominated by a single species. Familiar examples of single-species wetlands include mangrove swamps, tidal marshes of salt marsh cordgrass (*Spartina alterniflora or Spartina patens*), cattail (*Typha* spp.) marshes, and papyrus (*Cyperus papyrus*) swamps. Species-rich herbaceous communities include calcareous fens with as many as 20 to 30 species of vascular plants and bryophytes per square meter. Intermediate examples include abandoned beaver ponds with 3 to 12 species per square meter and a range of coastal wetlands (bottomland hardwoods, wet prairies, fresh marsh, and salt marsh) from the southern United States with 1 to 17 species per square meter.

Change in plant species composition across gradients within wetland sites depends on the amount of change that occurs within a site in the physical and chemical variables controlling species distributions. A single small depression may encompass a wide range of water depths and the associated changes in species composition. Although adjacent zones may share some species, the deep-water end of the gradient, which may be dominated by floating or submerged species, shares no species with the sedge- and forb-dominated wet meadow zone at the other end of the gradient. Depending on the slope and width of the floodplain, wetlands along major rivers may include areas that experience very different frequencies of flooding and consist of very different plant communities, from the open water and marshes of backwater sloughs to hardwood-dominated forests along natural levees. Erosion and deposition of sediments within the floodplain create surfaces of varying ages that support plant communities of different successional status and composition. Much of the species diversity in the Peruvian Amazon has been attributed to the heterogeneity created by long-term patterns of erosion, deposition, and plant succession.

In other wetlands, environment changes little over relatively large distances, for example, where the accumulation of peat has filled in basins and minimized topographic changes. Though the presence of hummocks and hollows introduces small-scale heterogeneity, mean water depth, pH, and nutrient availability change little as one moves across the bog surface. Plant species composition in plots spaced at great distances, but at equivalent microtopographical elevation, may be quite similar.

Although many studies have examined plant species richness in small plots, systematic comparisons are difficult to make because plot size and sample number vary among studies. Given that species richness is known to increase with increasing sample area, conclusions cannot be drawn about relative richness among samples if sample areas are not equal. Nonetheless, some general statements can be made. First, the number of plant species present generally decreases as water depth and frequency of saturation or flooding increase. For example, in his study of Wisconsin plant communities, Curtis (1959) reported that the average number of species per stand ranged as follows: 7 in stands of submerged aquatics, 11 for emergent aquatics, 28 to 29 in sedge meadows, 44 in wet prairie, and 62 in wet-mesic prairie.

Second, the effect of moving water on diversity depends on flood velocity, magnitude, and frequency. Some degree of disturbance from flooding increases diversity by removing live biomass and litter, thereby creating openings for germination of new species. Extreme or very frequent flooding, however, lowers diversity. Few species can withstand both the high stress of extended periods of anoxia and the frequent disturbance of biomass removal.

Third, the vegetation of saline wetlands tends to be less species-rich than freshwater wetlands. For example, coastal salt marshes of the eastern United States rarely contain more than two species in 0.25-m^2 plots (**Figure 3**). Plots of comparable size in freshwater herbaceous communities frequently contain 10 or more species. Increasing the plot size in salt marshes adds few species but is likely to significantly increase species number in many types of freshwater wetlands. For example, the number of vascular and bryophyte species in rich fens in New York increases from about 20 in 1-m^2 plots to 40 in 25-m^2 plots to 65 in 100-m^2 plots (**Figure 12**).

Fourth, in the temperate and boreal zones, *alpha* diversity generally increases across the range of peat-land types from bog to rich fen for vascular species. Continental raised bogs in eastern North America may have only 20 to 25 vascular species per site, one of the most impoverished vascular floras in North America. Rich fens may contain as many as 140 vascular species at a single site. The bryophyte diversity also tends to increase from bogs to rich fens in eastern North America. Continental raised bogs usually have fewer than 20 species of bryophytes in 100 m^2 while rich fens usually have between 20 and 60 bryophytes in a similar-sized plot. However, Vitt and others (1995) reported that bryophyte diversity in peatlands of continental western Canada could be similar for bogs and

Figure 3 Salt marsh in southern New Jersey, USA.

fens. Species richness in larger plots (2500 m^2) ranged from about 5 to 24 in bogs and poor fens and from about 5 to 28 in rich fens. Thus, even though the highest species richness was found in extreme rich fens, any individual bog could contain as many species of bryophytes as a rich fen. At the landscape scale, rich fens are distinctly more species rich than bogs and poor fens. Because their species composition varies more among sites, rich fens have greater diversity when an entire region is considered. In both Britain and continental western Canada, bogs have only about half the number of bryophyte species as fens.

Fifth, relative to the landscapes in which they occur, many types of wetlands appear to be islands of diversity. Fens in northeastern Iowa support 28% of the regional and 18% of the total state flora even though they currently cover only 0.01% of the land surface. Boreal old-growth swamp forests constitute only 5% of Sweden's forest land area but harbor more than half of all vascular forest plant species found in Sweden and about a third of the total Swedish boreal flora of bryophytes. Almost a third of the federally listed threatened and endangered plant species in the United States are wetland dependent. Furthermore, for some types of wetlands, rare and uncommon plant species tend to be associated with the most species-rich sites.

Finally, latitudinal patterns in plant species diversity of wetlands do not appear to parallel those for terrestrial environments. In sharp contrast to terrestrial habitats, wetlands in the tropics are not necessarily more species rich than those in the temperate and boreal zones. According to Ellison 2004, the mangrove swamps, palustrine forested wetlands, palm swamps, and hardwood swamp forests of Central America all exhibit low species diversity. On the basis of a comparison of representative aquatic families and aquatic habitats, Crow (1993) also concluded that aquatic plant diversity was higher in both warm and cool temperate latitudes than in the tropics. On the other hand, some tropical wetlands can be highly diverse. Ellison 2004 reported high plant species richness (292 species of 0.5 m in height or greater) in riparian forest fragments in Belize. Additional systematic and standardized studies are needed to address this issue.

Major Groups of Wetland Animals

In terms of abundance, biomass, and species richness, macroinvertebrates are the most important wetland-dependent animals in freshwater wetlands. Four groups—the insects, mollusks, crustaceans, and annelids—make up the majority. The aquatic insects are the most functionally and taxonomically diverse, and include forms that occur throughout all habitats (the bottom, deep waters, and shallow, vegetated areas) in most wetlands. The midges (Chironomidae, Diptera) constitute perhaps the most widespread group of aquatic insects, and larval forms of midges typically represent the most abundant macroinvertebrates in wetlands. Other ecologically important, widespread groups include the mosquitoes, dragonflies and damselflies (Odonata), mayflies (Ephemeroptera), caddisflies (Trichoptera), stoneflies (Plecoptera), craneflies (Tipulidae), and water beetles (e.g., Corixidae, Belostomatidae, and Notonectidae). Among these groups, only the water beetles are entirely aquatic; members of other groups typically have aquatic larval stages that undergo a synchronized transformation ("hatch") into adult forms, which may live for periods ranging from 1 to 2 days (some mayflies) to weeks or months (many dragon-flies).

The mollusks include the many species of filter-feeding clams and herbivorous snails. The most widespread and common are fingernail clams. Larger clams and mussels are equally widespread but less common, although they are sometimes abundant along large rivers and lake fringes. Most large clams dwell on the bottom of wetlands, whereas the fingernail clams often occur in submerged vegetation. Snails also occur in many wetlands and live upon stems, stalks, and leaves of aquatic vegetation, and graze on epiphytes.

The crustaceans, like the aquatic insects, are commonly encountered throughout most freshwater wetlands. Especially common in open-water and upon aquatic vegetation are isopods and amphipods. In protected open water areas, small zooplankters, including cladocerans and copepods are abundant. Crayfish are common bottom-dwelling crustaceans in many wetland ecosystems. The last major group of aquatic invertebrates, the annelids (mainly oligochaetes), are not particularly diverse taxonomically. However, they can be extremely abundant in some wetlands, where they burrow in the wetland bottom or attach to aquatic vegetation.

Vertebrate animals represent another important component of the wetland fauna and include the amphibians, reptiles, fishes, birds, and mammals. The amphibians are composed of two main groups, the frogs and toads, and the salamanders. Most species of frogs and toads have complex life cycles that include an aquatic, usually herbivorous, larval stage adapted for rapid growth (the tadpole stage), and a terrestrial, carnivorous adult stage adapted for dispersal among wetlands (**Figure 4**). Their relative use of wetlands versus uplands varies among groups. For example, the major group of frogs in North America, the Ranidae, includes (a) members that may be mostly terrestrial but return to wetlands to breed and sometimes to overwinter (e.g., members of the leopard frog complex, e.g. *Rana pipiens*) and (b) other species (e.g., bullfrogs, *Rana catesbeiana*) that are primarily aquatic and typically leave wetlands only to disperse to new areas.

Figure 4 Frog and duckweed in freshwater marsh in upstate New York, USA.

Among North American salamanders, all are wetland dependent except for members of the Plethodontidae, although even this family includes the Desmognathinae, a large group of stream-associated species. In salamanders, wetland dependency ranges from strictly aquatic (e.g., mudpuppies (*Necturus*), hellbenders (*Cryptobranchus*), Conger eels (*Amphiuma*), and sirens (*Siren*)), to semiaquatic in groups that spend much of the growing season in wetlands but overwinter on land (e.g., newts (Salamandridae)), to primarily terrestrial species that return to wetlands only to breed (e.g., the vernal pool-breeding mole salamanders (Ambystomidae)).

In terms of numbers, species richness, and biomass, the majority of wetland fishes are small forage fishes. In North America, the primary groups are the killifishes (*Fundulus*), shiners (*Notropis*), sunfishes (*Lepomis*), and mosquito fishes (*Gambusia*). In deeper-water wetlands or wetlands connected to permanent water bodies, larger, bottom-feeding species occur, such as Ictalurid catfish (e.g., bullheads) and carp (*Cyprinus carpio*), as well as carnivorous species such as pickerel (*Esox*), perch (*Perca*), and bass (*Micropterus, Morone*).

Turtles are the most diverse group of wetland reptiles. Most turtles are highly aquatic and leave water only to lay their eggs and to disperse to new habitats. Commonly encountered, highly aquatic turtles in North America include the snapping turtle (*Chelydra serpentina*), mud and musk turtles (Kinosternidae), and softshells (Trionychidae). The Family Emydidae includes many other highly aquatic turtles, such as cooters, sliders, painted turtles (*Pseudemys and Chrysemys*), map turtles and sawbacks (*Graptemys*), and terrapins (*Malaclemys*), as well as other partially aquatic species that travel regularly among disjunct wetlands (e.g., spotted turtle (*Clemmys guttata*)) or that use wetlands only for hibernation (e.g., wood turtles (*Clemmys insculpta*)). Other wetland-dependent reptiles include the water snakes (e.g., *Nerodia*) that use wetlands primarily for feeding on fish, frogs, and crayfish, and rest above water on hydrophytes or on land at other times. Most wetland-dependent snakes are viviparous, that is, bear live young, and therefore do not undertake migrations to terrestrial habitats to lay eggs, as do turtles. Many other snakes, however, and some lizards, live primarily in uplands but feed opportunistically in wetlands (e.g., king snakes (*Lampropeltis*), rat snakes (*Elaphe*), and garter snakes (*Thamnophis*)).

Several large groups of birds occur nearly exclusively in wetlands. These include many carnivorous (mainly fish-eating) species, such as the loons (Gaviidae), herons and bitterns (Ardeidae), several waterfowl species (Anatidae), the kingfishers (Alcedinidae), terns (Sternidae), and several raptors (Accipitridae, e.g., ospreys (*Pandion haliaetus*)). Omnivorous groups include the grebes (Podicipedidae), many species of diving and dabbling ducks (Anatidae), cranes (Gruidae), rails (Rallidae), and gulls (Laridae). Primarily insectivorous species include the shorebirds (Charadriidae) and many songbirds. Unlike other wetland inhabitants, birds are highly mobile and often use disjunct wetlands seasonally or even daily (**Figure 5**).

The last group of wetland-associated vertebrate animals, the mammals, include few, wholly wetland-dependent species. Most prominent are rodents such as the muskrat (*Ondatra zibethicus*) and beaver (*Castor canadensis*). Other obligate wetland mammals include several primitive, carnivorous shrews

Figure 5 Foraging assemblage of scarlet ibis and barefaced ibis in the seasonally flooded grasslands of central Venezuela (Apure state). Photo by Mark Gregory.

("water shrews" in the genus *Sorex*), some lagamorphs such as the swamp rabbit (*Sylvilagus aquaticus*) and marsh rabbit (*S. palustris*), and mustelids such as the river otter (*Lutra canadensis*). Wetlands are a critical resource, however, for many otherwise terrestrial species, which use wetlands for feeding and cover, such as moose (*Alces alces*), raccoon (*Procyon lotor*), and mink (*Mustela vison*).

Animal communities of saltwater wetlands can differ substantially from those in freshwater systems because of the effects of salinity on animal metabolism. Generally speaking, analogous taxa occur in freshwater and saltwater wetlands, such that similar niches are occupied, but species richness of animals generally declines along a freshwater-brackish-saltwater gradient. Reptiles from the Gulf of Mexico region provide an example: about 24 species occur in fresh marsh, 16 in brackish marshes, but just 4 in salt marshes. Of the salt marsh species, few are salt marsh specialists. Some terrapins are largely restricted to salt marsh habitats, but other regularly encountered salt marsh inhabitants, such as cooters and alligators, actually prefer freshwater situations. Amphibians show a particularly sharp trend along the wetland salinity gradient. Owing to their highly permeable skins and inability to counteract the drying conditions produced by high osmotic pressures of salt water, very few species can survive in saline wetlands and even then occur only infrequently (e.g., some toads).

Relatively few breeding birds specialize on salt marsh habitats, although sparrows and rails are well represented. However, salt marshes are noted for their importance as stopover sites for the vast populations of migrating species that breed in freshwater wetlands that freeze in winter. Waterfowl, shorebirds, songbirds, and owls can occur in brackish and salt marsh habitats in large numbers during the colder months resulting in very diverse, if unstable, assemblages during the winter period. Thus, though occupied for relatively short periods, and not by a large number of breeding species, coastal marshes nevertheless are a critical habitat in the annual cycle of many bird species.

Mammal communities in saltwater wetlands are generally quite species poor. However, the occasional effects of high densities of aquatic rodents (e.g., muskrats and nutria) can

be of ecological significance. As in freshwater systems, these species can radically alter the wetland environment through so-called "eat-outs" of the vegetation. Otherwise, saline wetlands are infrequently visited by species more dependent on freshwater wetlands, such as otter, mink, or raccoon.

Overlap of freshwater and marine species, in conjunction with resident species that can tolerate the substantial fluctuations in salinity, produces highly complex, species-rich assemblages of fish and crustacean species in saltwater wetlands. Though characteristically species rich, these assemblages are temporally quite unstable because of daily tidal cycles, with freshwater-associated species descending into salt marsh systems on outgoing tides and marine species arriving on incoming tides. In particular, many marine fishes and crustaceans, especially shrimp, use salt marshes as nursery areas, particularly for post-larval and juvenile forms. Here they take advantage of the lower numbers of predators in salt marshes relative to the open ocean and have access to the high productivity of salt marshes.

Controls of Species Diversity

Within particular wetland ecosystems, plant and animal diversity reflects the interacting influence of a number of abiotic and biotic variables that operate across a range of spatial and temporal scales. Diversity in wetlands cannot be understood without attention to these gradients, the scales at which they operate, and their interactions. Of the physical and chemical variables, hydrologic regime, mineral ion concentrations, pH, nutrient availability, salinity, and disturbance have been shown to play particularly strong roles. They largely determine the number of species that are physiologically capable of living in a site. Important biotic variables include primary productivity and interspecific competition. Along with abiotic factors, they influence which plant and animal species actually occur within the site. Because the composition, structure, and density of vegetation form key elements of habitat for animal species, these gradients also strongly influence animal diversity.

Depending on the type of wetland, different abiotic and biotic variables assume greater or lesser importance in determining species distributions. Hydrologic regime is important in all wetlands for both plant and animal species. Saturation with water severely restricts diffusion of oxygen into the soil while microbes rapidly deplete available soil oxygen. Hydrologic regime, therefore, largely determines the distribution and frequency of the most universal stress to which wetland plants and animals must adapt—anoxia in the water column, shallow soils, and rooting zone of plants. Salinity generally assumes importance only in coastal wetlands and in the saline wetlands of semiarid and arid regions. However, inland salt marshes occur in the Great Lakes region and some of the wetlands of the prairie pothole region of North America are saline. Mineral ion concentrations and pH affect species composition in all types of wetlands but have particular significance in peatlands that exhibit both extremes of the gradient in these factors. The combination of low nutrient availability, low pH, and low concentrations of calcium and magnesium makes bogs inhospitable environments for most plant and animal species. The extremely high pH and calcium concentrations of some rich fens are associated with high species richness and a large number of rare and uncommon species of plants and snails. Nutrient availability, which is lower in all undisturbed peatlands than in mineral soil wetlands, has become an issue for many types of wetlands as humans have increased nutrient inputs to wetlands.

Flowing water, especially at faster rates and larger volumes, exerts an additional mechanical stress on wetland species in some environments. Plants growing in river floodplains, tidal marshes, and other wetlands subject to flooding with rapidly flowing water must be able to withstand the force of moving water or must have life histories that allow them to germinate and reproduce in periods between floods. Well-developed root systems and flexible stems are essential for perennial plant species. Animals in these environments must be able to move out of the reach of flood waters, either into sediments or the tops of trees or out of the flooded area.

Many types of disturbance—factors that remove plant biomass—affect wetland diversity. Extended periods of inundation with deep water kill most emergent plants, which allows new species to germinate when water levels drop. Muskrats and nutria eat marsh vegetation. Moose consume wetland shrubs and aquatic vegetation. Beavers fell trees, alter hydrologic regimes with their dams, and destroy existing vegetation in digging for mud to strengthen the dam. The flooding created by beaver ponds destroys flood-intolerant vegetation. Tides and storm surges deposit patches of debris that bury vegetation in coastal wetlands. Hurricanes rip trees out of swamps and deposit sediment and other debris in wetlands. Humans harvest timber from swamps in many parts of the world. In Africa, southeastern Asia, and parts of South America, humans harvest other wetland plants for various uses, including firewood, food, and shelter. Reeds (*Phragmites communis*) are still harvested in The Netherlands and England as thatching for roofs.

Change over time as well as space is the rule in wetlands. Because climate drives hydrology, seasonal, annual, and longer-term changes occur in water depth and all the chemical and physical factors it regulates. Extended periods of wet or dry years dramatically change the distribution of both plant and animal species. Some wetlands systems, such as the prairie potholes of North America, have 10- to 20-year cycles of wet to dry climate. In other regional wetlands, such as the deep-water cypress swamps of the southeastern United States, wet to dry cycles occur over much longer time periods. The effect of this temporal variation at many scales is to increase overall species diversity by promoting a dynamic community composition and spatial distribution among years. In wetlands where organic matter accumulates as peat, even more dramatic changes occur with time; the landscape itself is transformed. Over hundreds to thousands of years, a mineral-rich, deep-water pond with high pH and relatively high nutrient availability can change to a raised bog with low pH, low nutrient availability, and low mineral ion concentrations (**Figure 6**). The plants and animals of a pond are replaced with those of the bog. Long-term deposition of mineral sediments in estuaries can create similarly dramatic changes in topography, landform, and the hydrologic regime for wetland organisms.

Figure 6 Raised bog, coastal Maine, USA.

Controls of Plant Species Richness

The question of what controls patterns in plant species richness is an old one that has received renewed attention with observed declines in species diversity over much of the globe. In wetlands, the question has been resolved only in part. The effects of many single factors are relatively well understood because of the over-riding importance of some physical and chemical variables in determining the pool of species physiologically capable of living in a site. Spatial and temporal heterogeneity, long recognized as critical determinants of species richness in other systems, are also positively correlated with species richness in wetlands. However, the relative importance of interacting sets of variables, operating in different types of wetlands and over different spatial and temporal scales, is only beginning to be understood. Because humans have increased nutrient inputs to many wetlands, the question of the relationship of plant species richness to nutrient availability, community productivity or biomass, and competition continues to motivate many wetland studies. Controls operating at regional and global scales have been little studied.

Gradients in several physical and chemical factors show strong correlation with species richness in wetlands, especially at the ends of the gradients where stress on plant growth is high. While more than 6700 species, approximately one-third of the total United States vascular flora, grow in wetlands, few species have evolved to persist in wetlands with low pH, high salinity, continuous inundation with shallow water, or high flooding frequency. Hence, bogs (low pH), the low marsh zone of salt marshes (high salinity), deep-water marshes (continuous inundation), and wetlands in the active channels of rivers (high flooding frequency) are all species-poor. In general, species richness increases with decreasing stress due to abiotic factors.

Numerous studies have shown that water level fluctuations are critical to maintaining species diversity in a wide variety of wetlands. Alternating periods of inundation and exposure of the soil create temporal and spatial gradients of water depth that provide conditions for germination of the largest number of species. Species diversity always declines when water levels are artificially stabilized. Several studies have shown that coastal plain ponds, Great Lakes shoreline vegetation, prairie wetlands, and Carolina bay wetlands all require fluctuations in water depth to maintain overall species richness.

Spatial heterogeneity increases the number of species co-occurrences in wetlands through a number of mechanisms. The presence of hummocks and hollows in peatlands creates small-scale gradients in pH and moisture that allow species with a wider range of tolerances to coexist in relatively small areas. The presence of mounds and tree bases in floodplain swamps provides sites for germination of a number of species that do not germinate or persist in standing water. Old muskrat mounds serve the same function in cattail marshes. Microtopographic variation in riparian wetlands causes spatial variation in flood frequencies that results in higher species richness. Deposition of wrack (dead plant debris) by tides and storms increases species richness in salt marshes by producing openings in dense stands of *Spartina*; these openings have higher salinity than the surrounding vegetation and are colonized by more salt-tolerant species (e.g., *Distichlis spicata*). High variation in substrate pH, type, texture, and age creates microhabitat variation along arctic, boreal, and tropical rivers and increases the number of plant species occurring in riparian vegetation.

Some of the spatial heterogeneity associated with higher species richness in wetlands results from various types of disturbance. In general, richness first increases and then decreases along gradients of increasing disturbance so that richness is highest at intermediate points along the gradient. In many environments, lack of disturbance allows a few highly competitive species to displace other species through the process of competitive exclusion. Disturbance disrupts this process and allows other species to persist. However, richness decreases if disturbance is too frequent because few species are adapted to very high disturbance frequencies.

Fertility, or nutrient availability, appears to be another strong control on plant species richness. However, few studies have actually measured nutrient availability because of the difficulty of doing so. Rather, nutrient availability has been inferred from surrogates such as community biomass, percent soil organic matter, or substrate texture. Use of these surrogates generally suggests that species richness is highest at moderate levels of community biomass and presumably, therefore, at moderate levels of nutrient availability. Close inspection of the data shows that richness can be low or high at low to intermediate levels of community biomass but almost always decreases above some threshold of high biomass. The amount of biomass at which that threshold occurs, however, varies greatly among wetland types. Furthermore, the relationship between richness and biomass appears to be scale-dependent. When data from wetlands with different vegetation types are examined, richness follows a unimodal relationship with community biomass. Within small plots within types, the relationship breaks down.

The complex interplay of abiotic factors with biological variables such as competition and productivity has been examined in only a few freshwater wetlands and seldom through experimental manipulation of variables. Salt marshes have received more attention. Results from these studies emphasize that the relative importance and direction of the effect of biotic variables on species richness change along gradients of stress. Abiotic variables play the strongest role where stress is high but the presence of some species can ameliorate the stress for other species (e.g., by lowering salinity through shading,

which decreases concentration of salts due to evapotranspiration). Species richness is thereby increased above what abiotic conditions might otherwise allow through positive interactions among species. Nonetheless, the number of species tends to decline monotonically with increasing stress from abiotic factors. Where stress in minimal, biotic control of species richness is greater. Here, variables related to density effects (e.g., productivity, biomass, light) are more likely to control variation in species richness, probably through competitive effects of dominant species on subordinate ones. In such environmentally benign wetlands, productivity is likely to be high and a few species are likely to dominate unless the process of competitive displacement is disrupted by disturbances that remove plant biomass and allow other species to establish.

The interplay of these local biotic and abiotic factors is played out against the background of regional and historical controls on the species pool (i.e., the number of species available to colonize a site). While local and current conditions determine which plant species do colonize a site, the regional species pool sets the upper limit to the number of species that could colonize the site. The geological, evolutionary, and ecological history of a region, along with its area, controls this pool. Geological age, processes of speciation and extinction, geographic dispersal, and chance historical events all leave their imprint on the species pools of particular regions. Few attempts have been made to relate the species pool to the number of species actually co-occurring in a site because of the difficulty of obtaining adequate data sets.

Controls of Animal Species Diversity

Patterns of diversity and productivity in wetland animals follow gradients strongly related to hydrologic regime, primarily because of its effects on the composition, structure, and productivity of wetland vegetation and on oxygen availability within the water column and wetland sediments. Oxygen levels most influence the distributions of wholly aquatic, nonmigratory wetland animals (i.e., the macroinvertebrates and fishes). The productivity and diversity of wetland invertebrates and fish, and, consequently, many water birds and mammals, are highest in semipermanent wetlands (e.g., those flooded during most of the growing season but dry otherwise). Most amphibians, however, occur in transient pools. Trends in reptile diversity and productivity along this inundation gradient are not clear.

Semipermanent and permanent water bodies are the primary habitats of fish, which generally lack the ability of many other wetland inhabitants to disperse overland or enter dormancy when wetlands dry. Thus, areas of sufficiently oxygenated water must occur in wetlands throughout the year to support fish populations, especially those of large-bodied species. Large, seasonally flooded wetlands with pools or channels that remain permanently flooded, and lakes with well-developed littoral vegetation tend to support the most diverse fish communities. Similarly, fish-eating birds and mammals frequent the habitats occupied by their fish prey. In contrast, temporary, unvegetated pools are the primary breeding habitats of amphibians, offering two main advantages. First, amphibian larvae are able to exploit a pulse of primary productivity that occurs shortly after pools fill with water. Second, temporary pools will not support fish, major predators on amphibian eggs and larvae.

Many other wetland animals exploit intermittently flooded wetlands. Waterfowl, particularly egg-laying females, frequently travel among shallow pools, ditches, and puddles to feed on the pulse of invertebrate production that occurs following flooding. These feeding pools often are remote from nesting areas at more permanent wetlands, where deep waters and dense vegetation protect nesting birds and their eggs from predators. Similarly, snakes and turtles often can be found in temporarily flooded wetlands, and seek refuge from subsequent low-water periods by migrating or entering dormancy in a wetland's sediments.

Much of the variation in cover and food for wetland fauna, and hence in animal diversity, is associated with variation in the species diversity, density, and structural characteristics of wetland plants. Many wetland animals show affinities for particular life-forms of hydrophytes (e.g., submerged plants, floating-leaved plants, or emergents), and some are associated with specific plant taxa. For example, most aquatic invertebrates seek protection from predation and safe oviposition sites in macrophytes. In general, plants with dissected leaves support more invertebrates than plants with broad leaves. Macroinvertebrate diversity and density generally are greater in vegetated than open water areas, and, within vegetated areas, are greatest in areas of mixed emergent and submerged vegetation. Shading by erect hydrophytes also influences macroinvertebrate abundance; unshaded areas of submerged vegetation often support dense populations owing, in part, to elevated water temperatures in unshaded areas. Similarly, shallow, vegetated wetland habitats fringing deep-water areas are critical nursery habitats for fishes, many species of which use stands of particular wetland plant species as spawning habitat. These areas provide protective cover for eggs and larval fishes and food resources for young fishes. Like aquatic insects, many fishes prefer unshaded, shallow areas where warm water temperatures hasten the development of eggs and larvae.

Two key water chemistry parameters that influence distributions and diversity of wetland animals are acidity and salinity. The relationship of acidity to the distribution of wetland animals can be complex. For example, many aquatic, fish-eating birds frequent wetlands with moderately acidic waters (pH 5.5–6.0). Although fish populations often are reduced in wetlands with waters of pH <6.0, suspended material may precipitate from the water column at low pH. The resulting increase in water transparency may improve encounter rates with prey and capture success for birds that pursue their prey underwater, and thereby compensate for decreased fish density. The reduction or loss of fish from moderately and strongly acidified waters also reduces competition between fish and insectivorous birds for macroinvertebrate prey. This may explain why dabbling ducks frequent waters of relatively high acidity that fish-eating ducks avoid. Highly acidic waters (i.e., pH <5.0) generally support few fish or amphibians and have low diversity of aquatic invertebrates. Water bird and mammal use of such wetlands is limited.

Salinity strongly limits animal diversity in wetlands, primarily through effects on the composition of plant and invertebrate communities and through its direct physiological

effects on wetland animals. Difficulty in maintaining water balance leads many dabbling ducks, particularly those brooding young, to avoid wetlands with highly saline waters. Owing to their highly permeable skin, amphibians are intolerant of even moderately saline conditions. For similar reasons, highly saline conditions often limit the survival and hatching success of fish eggs and survival of larval fish. Many mammals, such as muskrats, are tolerant of highly saline conditions, but populations often are limited by the low quality of forage plants that grow in saline wetlands.

Three spatial characteristics of wetlands and their distribution in the landscape—size, connectivity, and isolation—also influence the diversity of wetland animals within and among sites. For example, small wetlands often support fewer species of birds than large wetlands, and isolated wetlands support fewer species than wetlands in complexes. Aquatic, fish-eating birds are particularly sensitive to wetland area and often shun small wetlands (<10 ha). Small wetlands may not provide a sufficient quantity of habitat or prey for many large-bodied species, and short inter-wetland distances may provide certain species with alternate foraging sites while minimizing their time in flight. Larger wetlands generally support a wider diversity of vegetative life-forms and, therefore, may provide a greater variety of habitats for wetland species than smaller wetlands. This may account for the frequently observed pattern of increased fish species diversity in larger than smaller wetlands.

The proximity of diverse habitat types within a wetland, and connectivity among wetland environments and with upland habitats, is critical to maintaining high diversity of wetland animals, particularly amphibians, some birds, and fish. Aquatic breeding and terrestrial nonbreeding habitats must be contiguous for amphibian populations to persist. Local breeding populations undergo frequent extinction and recolonization events, and individuals often are exchanged among populations. The importance of migration in amphibian population ecology is indicated by the presence in many species of a juvenile stage adapted strictly for dispersal. Destruction of larval or adult habitats, or the connections between them (e.g., riparian corridors) often drives local amphibian populations to extinction.

Proximity of diverse habitat types within a wetland is critical to many breeding water birds and fish. Some water birds, such as rails, dwell within dense stands of emergent vegetation, while others, such as bitterns, herons, and shorebirds, forage mainly along the interface of wetland vegetation and open water. Still others, such as grebes and many dabbling ducks, are associated with floating and submerged vegetation, while loons and cormorants forage in deep, open waters. Most of these birds, however, build their nests within dense stands of emergents, on small islands, or in trees or shrubs.

Fish assemblages provide another example of the importance to wetland animals of spatial heterogeneity and connectivity in wetland habitats. Most large species of bottom-feeding and predatory species undergo small-scale migrations between feeding and spawning areas in shallow wetlands and resting areas in deeper, open-water habitats. These migrations often occur nightly, with fishes returning to deep waters to rest during the day. Critical to these migratory movements are the links established between shallow, vegetated areas and deep-water zones by seasonal regimes of wetland flooding. Finally, many fishes undergo seasonal migrations over hundreds of kilometers into river floodplains and return to the river channels as waters recede.

Some wetland animals create some of the spatial and temporal heterogeneity that promotes animal diversity in wetlands. Beavers alter stream channels and transform riparian forests into freshwater marshes and ponds with stands of dead timber. Beaver activities also permanently modify soils beneath dam sites and even change local topographies; beaver dams reduce current velocities and cause massive silt depositions, which remain long after the dams disintegrate. High levels of herbivory by muskrats and geese can result in "eat outs," whereby essentially all emergent plant material in a marsh is consumed over a few years. Such drastic, animal-caused modification of the wetland environment not only affects habitat availability for other wetland animals but can alter patterns of energy flow and biotic productivity within wetland ecosystems. Other, less drastic examples of habitat modification include the activities of alligators, which construct small basins that serve as critical refuges for many fishes, and important feeding areas for fish-eating birds, during low water periods (**Figure 8**). Crayfish burrows serve in many areas as moist refuges for water snakes, salamanders, and frogs.

Functional Diversity

Wetland plants exhibit a diverse array of adaptations that allow many species to tolerate stresses associated with soil saturation, alternating periods of flooding and drought, high salinity, low pH, and low nutrient availability. Other adaptations assist wetland plants in dispersal and establishment. Animals also exhibit an array of adaptations to wetland environments, although unlike plants, many simply can move to escape stresses. Collectively, these adaptations explain much of the high species richness and diversity of many wetlands, especially those with strong hydrological and chemical gradients.

Adaptations to Anoxic Environments

Many wetland plants have one or more morphological and anatomical adaptations that allow them to tolerate soil saturation and anoxia for short to long time periods, primarily by allowing more oxygen to reach the plant root system. Key morphological adaptations include (a) aerenchyma, air spaces in roots and stems that allow oxygen diffusion from stems above water to roots; (b) hypertrophied lenticels, enlarged openings in stems and roots that allow gas exchange between internal plant tissue and the atmosphere; (c) adventitious or stem roots developed above the water line; and (d) the ability to grow new roots under anoxic conditions. In black mangrove (Avicennia), pneumatophores, vertically growing air roots, absorb oxygen that is transported to the connected, submerged, lateral growing roots. Prop roots of red mangrove (*Rhizophora*) function in much the same way. In both mangrove species, oxygen enters the plant through lenticels exposed above water and diffuses to roots in anoxic sediments.

Many woody species of alluvial floodplains have extensive, shallow root systems placed where sediments are least likely to experience oxygen deficits.

Plant physiological adaptations generally involve tolerance to low soil oxygen and specialized chemical reactions. Specialized reactions include an accumulation of malate instead of ethanol, the production of high levels of nitrate reductase, and a reduction in ethanol production by reducing alcohol dehydrogenase activity. Additionally, rhizosphere oxygenation is an important mechanism for many species and can lessen toxic concentrations of some anaerobic soil compounds.

Wetland animals, with their characteristically high metabolic rates, have developed a variety of adaptations to low levels of oxygen and carbon dioxide. Perhaps most obvious is development of specialized regions of the body for gas exchange. Examples include gills in fish and crustacea, parapodia in polychaetes, and highly vascularized tissues on the lower lips of some tropical fishes or in the cloacas (urogenital openings) of turtles. Other physical adaptations include modification of respiratory pigments to improve oxygen-carrying capacity in invertebrates. For example, midge larvae (*Chironomus*) are often colored brightly red, indicating the unusually high concentrations of hemoglobin present in these organisms, permitting them to survive long periods of hypoxia. Some vertebrates, particularly fishes, also increase densities of circulating red blood cells and thereby their oxygen-holding capacity.

Physiological adaptations of animals primarily involve shifts in metabolic pathways. For example, bivalves use alternative biochemical pathways, primarily a switch to glycolytic fermentation, to increase energy production under anoxic conditions. Some invertebrates also diversify the by-products of glycolysis to avoid toxic accumulation of any single compound, particularly ethanol. Turtles are remarkable for the ability of these lung-breathers to remain under water submerged in sediments for months during the winter season. Biochemical adaptation for natural anoxia tolerance in turtles includes well-developed antioxidant defenses that minimize or prevent damage by reactive oxygen species during the reoxygenation of organs after anoxic submergence. Last, many invertebrates store large quantities of respirable carbohydrate, usually glycogen, for breakdown and oxygen-liberation during periods of anoxia.

Behavioral adaptations also are critical and widespread, including dormancy or low locomotor activity during periods of oxygen stress, and migration from hypoxic to oxygen-rich environments. Many animals in low-oxygen situations have developed means of moving water more rapidly across respiratory surfaces. For example, benthic animals often use a variety of behavioral means (fanning, retreating into and out of burrows) to ventilate their burrows and increase the water flow across membranes during times of hypoxia.

These adaptations combine in interesting ways in particular taxa. Some fishes highly adapted to mud and shallow-water swamps cope by aestivating in mucous cocoons or by migrating overland while air breathing through modified swim bladders (e.g., lungfish). Some aquatic microinvertebrates, such as Collembola (spring-tails) and mites (Acari), have developed a "physical gill" that traps air gathered at the water surface in body surface hairs. Breathing of the trapped air, while underwater, occurs via a tracheal system, which opens to the body surface. Some aquatic insects, including mosquito larvae and chrysomelid beetles, tap the air within the aerenchyma of plant roots using a highly specialized, spinelike siphon attached to their abdomens. Last, some fly larvae use snorkel-like devices that extend above the surface of liquid mud or anoxic water and that permit the animal to air-breathe while remaining submerged in the anoxic substrate.

Adaptations to Salinity and Drought

Although halophytes (i.e., plants capable of persisting in saline environments) are not restricted to wetlands, these species dominate saline wetlands, such as inland and coastal salt marshes, and coastal fringe forests. Some species, such as various mangroves (*Avicennia*, *Laguncularia*, and *Rhizophora* spp.), are facultative halophytes and have mechanisms to inhibit salt absorption by their roots and to excrete salt from their leaves. Because nonhalophytes ("glycophytes") exhibit a range of tolerance to a salinity gradient, salinity and flooding regime determine plant species composition and richness along a gradient from salt marsh to tidal freshwater marsh. Plant species that use the C_4 pathway of photosynthesis are well adapted to habitats subjected to drought stress. Saline wetlands, therefore, often are dominated by C_4 plant species because the salt content makes water uptake more difficult. Plant species with C_4 photosynthesis are much more efficient in fixing carbon and in water use and have higher rates of net photosynthesis, growth, and dry matter production than C_3 plants.

Little is known about adaptations of wetland animals to salt stress. The fundamental problem of salt stress is its effect on water movement at the cellular level, which interferes with metabolic processes. Most simple microinvertebrates are osmoconformers whose internal salt concentration tracks that of the external environment. More complex wetland animals, particularly vertebrates, typically osmoregulate—that is, retain internal salt concentrations independent of those external to the body. Osmoregulation primarily involves moving ions across body membranes against the concentration gradient and is thus an energy intensive process. This process is usually associated with specialized renal organs (kidneys and antennal glands) and salt-secreting nasal or rectal glands. Behavioral adaptations, particularly short-term migrations, are common in mobile species. In such a manner, both freshwater and marine species can occur in salt marshes, retreating during unfavorable periods either upstream (freshwater species) or downstream (marine species) during the course of the daily tidal cycle.

Adaptations to Low Nutrient Availability and High Acidity

Nitrogen fixation is relatively uncommon in wetland vascular plants but the few examples are noteworthy. Nitrogen fixation by sweet gale (*Myrica gale*) can contribute 3 to 4 g N m^{-2} yr^{-1} to *Sphagnum* bogs. Nitrogen fixation rates of speckled alder (*Alnus rugosa* = *A. incana ssp. rugosa*) have been measured at 85 to 167 kg N2 ha^{-1} yr^{-1}. Some nonsymbiotic, aerobic and anaerobic bacteria, and blue-green algae are also significant nitrogen fixers in wetlands (**Figure 7**).

Figure 7 Acidic peatland, coastal Maine, USA.

Figure 8 Alligator in pool at Everglades National Park, southern Florida, USA.

Figure 9 Yellow pitcher plants in pocosin, South Carolina, USA.

Figure 10 Acidic peatland in the Adirondacks, New York, USA.

Most of the carnivorous species in the world occur in wetlands and other oligotrophic habitats. The relationships between insect capture, mineral nutrition (particularly nitrogen and phosphorus), and plant growth and reproduction have been investigated for numerous species. The relatively large diversity of organisms that can survive in the "pitchers" of some carnivorous plants also has been studied (**Figure 9**). Although benefits to carnivorous plants have been demonstrated, there is limited evidence that carnivory is necessary for most species to survive.

Evergreen, sclerophyllous shrubs that generally belong to the Ericaceae (heath family) are characteristic of nutrient-poor peatlands. The role of this foliage type in wetlands is uncertain, but it has been suggested that plant species with evergreen leaves may be more efficient in using nutrients than species with deciduous leaves. These leaves, which persist for up to four years, extend the period that the plant can photosynthesize, which conserves energy in the plant because all of the leaves do not have to be renewed each year. Furthermore, evergreen species tend to resorb more nutrients from senescing leaves than other species, thus increasing nutrient use efficiency. High nutrient resorption and long retention of nutrients in evergreen sclerophyllous leaves may be especially important in phosphorus-poor habitats such as bogs.

One of the most important groups of plants in colder, generally acidic wetlands of the world are *Sphagnum* mosses, a large genus consisting of more than 135 species (**Figure 10**). These mosses can thrive in conditions highly stressful to most plants (e.g., low pH, low nutrient availability, and saturated soils). They are the primary peat producers worldwide and have the capacity to modify the environment in ways that favor their own growth. Once established, *Sphagnum* mosses can further acidify their environment through cation exchange processes and by excretion of polygalacturonic acids. They

also paludify their environment through their high water-holding capacity and their role in peat accumulation which can block water drainages. *Sphagnum* species also can tolerate great desiccation. Three major gradients exert the greatest influence on the bryophyte flora of peatlands: acidity–alkalinity, dry–wet, low light-high light. Numerous *Sphagnum* species can occur even within a relatively small peatland because of the affinities of particular species to very specific pHs, other water chemistry variables, height above water table, and light.

Adaptations to Reproducing in Wetlands

Seeds of many wetland species have features that enable their dispersal by water (hydrochory). Red mangrove (*Rhizophora mangle*) produces seeds that germinate while on the parent tree, resulting in viviparous seedlings. The germinated seed can root if it lands on sediment. Otherwise, the seedling floats until a suitable substrate is reached.

Seed banks, the store of seeds that accumulate in soils, play a critical role in the long-term vegetation dynamics of many types of wetlands worldwide. Seed banks allow wetland vegetation to adjust to rising and falling water levels and help maintain compositional diversity across water depth gradients and from year to year and over longer climatic cycles. Most wetland species do not germinate under water and only a few survive more than a year or two of continuously deep water. A series of wet years can eliminate most vegetation, but when water levels fall, many species that existed only as seeds in the seed bank germinate in the wet exposed mud. Thus, fluctuating water levels and seed banks drive wetland succession. Seed banks are particularly important in maintaining the species composition and zonation of wetlands that have a large number of annual species (e.g., tidal freshwater marshes). An understanding of the seed bank is essential in wetland management, especially in restoration efforts.

Seed density in wetland soils, usually determined by germination tests, typically ranges from 1000 to 14,000 seeds $m-2$ with density and viability decreasing with increasing depth in the substrate. Graminoids (grasses and sedges) are often the most abundant group in wetland seed banks, with seeds of broad-leaved herbaceous and woody species far less abundant. Although the composition of the seed bank and plant species present in the wetland can be highly correlated, in many cases the seed bank harbors a much greater species richness than found in the extant vegetation. Seeds of some species are transient, while others can persist for decades.

The greatly enlarged, rounded bases of water tupelo (*Nyssa aquatica*) (**Figure 11**) and buttressed bases of bald- and pond cypress (*Taxodium spp.*) develop especially in deeply flooded conditions. These swollen bases likely aid in anchoring the tree. The "knees" of *Taxodium* also may function in this manner. *Taxodium* buttresses appear to provide a refugium above water for numerous species of herbaceous and woody plants that become established in the crevices where organic materials have accumulated over time. In some deep-water swamps, alternative colonization sites are limited for many plant species.

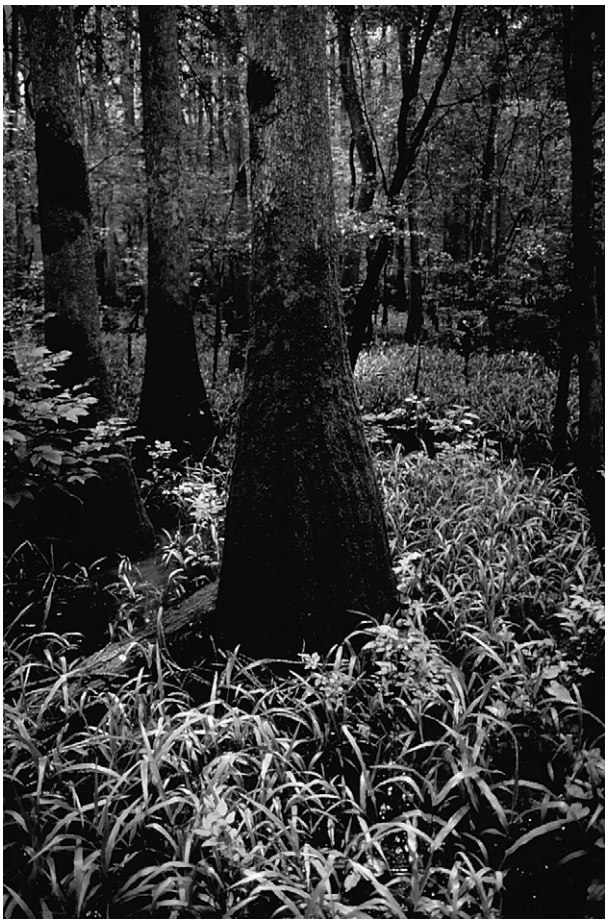

Figure 11 Water tupelo in southern deepwater swamp, South Carolina, USA.

Threats to Wetland Diversity

Worldwide, the loss of wetlands is estimated at about 50%. Functionally, the losses are much greater because extensive areas of boreal wetlands have been little altered while many different types of regional wetlands have been reduced by 80 to 90% elsewhere (e.g., California, southern Ontario, southwestern France, New Zealand). Wetland diversity and numerous plant and animal species have been impacted by a host of anthropogenic activities and natural disturbances for centuries. While single and cumulative effects of these activities have been assessed for many wetland species (primarily wildlife) and functions, few studies have examined the effects of these activities on species diversity. Because human activities often modify wetland hydrology and water chemistry, one should expect significant changes in diversity given the well-established relationships between wetland hydrology, water chemistry, and species distributions.

Despite the relatively recent appreciation of wetland functions and values, wetlands continue to be destroyed. A notable example is the Pantanal of Brazil, the world's largest wetland and home to many endangered or threatened plant and animal species. Various development plans, including

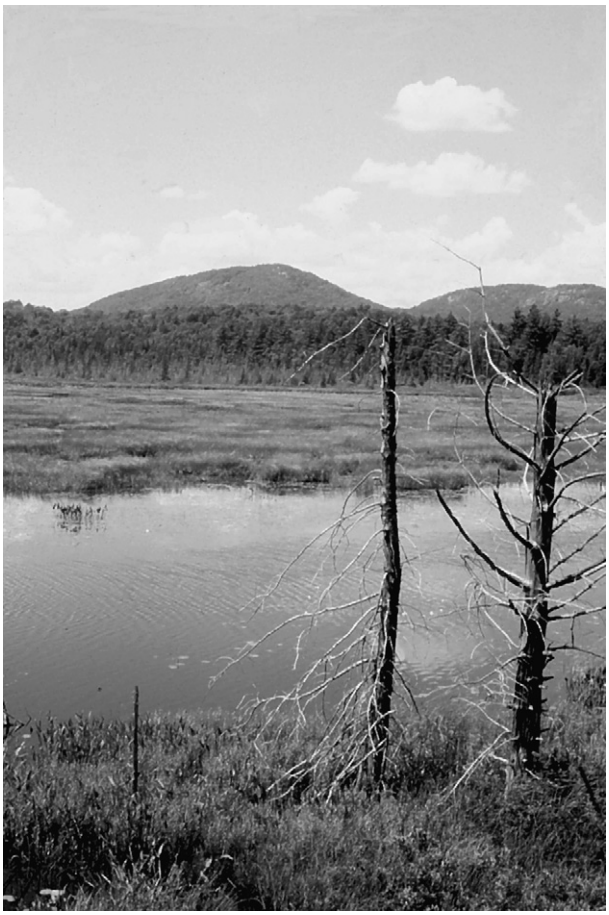

Figure 12 Freshwater marsh in the Adirondacks, New York, USA.

dam and highway construction, threaten the diversity of this vast wetland. Although some human activities may be able to be carried out in a sustainable manner in wetland habitats, habitat preservation is the key to preserving wetland diversity around the world.

Direct Habitat Destruction

By far, the majority of palustrine wetland loss in North America has been due to agricultural activities, especially direct conversion of wetlands to agricultural land. Agricultural uses have converted over 80% of the Mississippi River bottomland hardwood forest. About 90% of the wetlands in California, Ohio, and Iowa have been destroyed, primarily for agriculture. Wetlands adjacent to agricultural lands also can be adversely affected because drainage effects can extend a significant distance into the wetland. Coastal wetlands, most first altered by agricultural activities, including grazing and salt production, are now impacted by draining and filling for urban and industrial development. Drainage of wetlands on organic substrates leads to accelerated decomposition, erosion of organic matter, and release of carbon dioxide (a "greenhouse" gas) into the atmosphere.

Riparian wetlands in the western United States can be seriously degraded by cattle grazing, which adversely affects the adjacent aquatic ecosystem. Wildlife species composition and diversity are modified because heavy grazing reduces the structural complexity of riparian wetlands.

Timber harvest, when done without extensive drainage and total land clearing, generally converts forested wetland to earlier successional stages, or changes species composition and structure. Logging, specifically the extraction of cut trees through mechanical skidding and transport of heavy log loads, adversely modifies soil physical properties. Early logging of southern forested wetlands was typically done with no regard for sustainability. Consequently, forest composition and structure were dramatically altered. Logging roads can modify wetland hydroperiods such that productivity is raised or lowered. Occasionally, especially in northern forested wetlands, a heavy timber harvest can raise the water table, flooding already established species and decreasing the regeneration sites for new plants. Whole-tree timber harvest of oligotrophic peatlands can greatly reduce a site's nutrient pool.

Tropical intertidal zones are being increasingly altered for mariculture, especially mangrove wetlands for shrimp farming. Many salt marshes have been ditched and diked, and often converted to impoundments, to favor waterfowl.

Peat extraction, primarily for fuel or horticultural uses, has destroyed millions of hectares of peatlands in North America, Great Britain, and northern Eurasia. Where the mined peatlands have been abandoned or actively managed for conservation values, the vegetation can slowly recover. Which species come to occupy the site depends on the hydrology of the site, availability of propagules, and time since abandonment.

Gravel and sand mining can adversely affect wetlands directly by habitat destruction, and indirectly by changing the hydrology and water chemistry of an adjacent wetland. These mining activities can be especially damaging to ombrotrophic and minerotrophic peatlands (e.g., bogs and fens) because many of the characteristic species occur at very specific water levels and chemistry parameters.

Direct Alteration of Wetland Hydrology

Humans alter wetland hydrology primarily by building dams at wetland outlets to regulate the depth and duration of inundation, and by constructing channels and ditches to drain wetlands and prevent prolonged flooding. Artificially regulated water levels often result in impoverished animal communities because few species of wetland animals have life histories adapted to the stable water regimes that result. This decrease in diversity occurs even where water control structures were originally built with the intention of benefiting wetland animals (e.g., at wildlife refuges). Management strategies for many water impoundments now seek to emulate the "natural" flooding regimes that were present before impoundments were built. Wetland drainage has obvious and drastic effects on wetland animal communities and has resulted in a loss of about half of the original habitat available to the wetland fauna of the United States. Among the most imperiled wetland habitats are the easily drained, intermittently flooded basins and pools that are critical to a large proportion of the wetland fauna.

Dam construction and water diversion projects also have significant effects on downstream riparian vegetation by altering peak and minimum flows, decreasing erosion and deposition of sediment, and lowering floodplain water tables. Altering the natural variability of river flow can adversely affect the species composition and structure of riparian wetland vegetation. Dredging, channelization, and levee construction have greatly impacted extensive wetland areas in the Mississippi River Delta.

Groundwater extraction is a primary cause of wetland modification because it lowers the regional water table and alters recharge and discharge patterns within the wetland and surrounding landscape. Irrigation with water supplied by aquifers that are recharged in part by wetlands has led to declines in the area of major regional wetlands in North America (e.g., the prairie pothole and Nebraska sandhills regions).

Although plant species of coastal wetlands may be well adapted to flooding, increases in the level or duration of flooding above that at which species have long persisted can cause serious deterioration of these wetlands. Sea-level rise and saltwater intrusion are important factors in the degradation and loss of wetland forests and coastal marshes in the southeastern United States. Increased flooding and salinity have been particularly damaging to forests dominated by baldcypress.

Landscape Fragmentation

Other human activities impoverish the wetland fauna in more subtle ways, even where wetlands receive nominal legal protection. Destruction of the uplands adjacent to wetlands destroys the habitat interface critical for amphibians and reptiles that migrate between wetland and upland habitats. Reductions in the connectivity among wetlands (e.g., by construction of roads and levees) blocks the migration routes of amphibians, fish, and birds, and can lead to local population extinctions. In contrast, dredging of canals that link major river systems causes sudden mixing of fish and reptile faunas that may have evolved in isolation for thousands of years.

Other Threats

Anthropogenic inputs of nutrients and toxins drastically alter the chemical environment of wetlands and render many sites unsuitable for wetland plants and animals. Atmospheric deposition of nitrogen and sulfur is particularly high in parts of western Europe but is also high in the northeastern United States. Atmospheric deposition may be especially damaging to peatlands dominated by bryophytes (mosses and lichens), because these species are very sensitive to changes in nutrients and acidity-alkalinity. Wetlands in agricultural landscapes receive excess nitrogen via ground water draining from agricultural fields and excess phosphorus primarily via surface water runoff. Residential development also contributes excess nitrogen and phosphorus to wetlands. Coastal oil spills can adversely affect the vegetation of salt marshes and tidal freshwater wetlands.

Invasive, exotic wetland species typically cause a substantial loss of native wetland species and greatly alter wildlife habitat. In otherwise arid regions, invasive species use substantial amounts of water and can desiccate watercourses. Invasive species generally respond favorably to altered hydrologic regimes, substrate disturbance, or changes in water quality, especially eutrophication. Introduction of exotic wetland animals, for example, carp, nutria (*Myocaster coypu*), and bullfrogs, outside their native range have greatly altered wetland environments throughout much of North America, mostly to the detriment of the native wetland fauna.

Purple loosestrife (*Lythrum salicaria*), an emergent, herbaceous species of Eurasian origin, has become a serious invasive species of open wetlands in eastern North America. A single individual of this species can produce an average of 2,700,000 seeds. Another very serious invasive species in wetlands of the eastern United States is the common reed (*Phragmites communis*), which can produce 200 to 300 culms m^{-2} in fresh and brackish wetlands through an extensive network of rhizomes. Recent biological control methods (i.e., leaf- and root-feeding beetles) appear promising for *L. salicaria*.

Salt cedars (*Tamarix* spp.) are rapid, arborescent invaders of riparian wetlands in the southwestern United States, especially downstream from dams where flooding is minimal. Another invasive tree species of riparian wetlands in the western United States is Russian-olive (*Elaeagnus angustifolia*). In southern Florida, the invasive tree, melaleuca (*Melaleuca quinquenervia*), has been aggressively colonizing shallow wetlands. Two other tree species that seriously threaten southern Florida wetlands are Australian pine (*Casuarina*) and Brazilian pepper (*Schinus terebinthifolius*). Glossy buckthorn (*Rhamnus frangula*) is becoming a serious problem in wetlands around the eastern Great Lakes basin.

Some native species become invasive following some hydrologic changes or an increase in nutrients and dominate wetlands previously occupied by other, more desirable species. Cattail is regarded as a threat to southern Florida marshes that have been dominated by sawgrass (*Cladium jamaicense*). The spread of cattail is believed due mostly to increased phosphorus input from agricultural lands and anthropogenic changes to the regional hydrology. Cattail is also considered a weed in many wetlands and aquatic habitats that are used for agriculture or to provide water resources (e.g., rice fields, irrigation canals, recreational lakes, and reservoirs). Mechanical (e.g., cutting, water level modification, fire, shading), chemical (selective versus nonselective herbicides), and biological control methods vary in their effectiveness, which varies widely among species. Maintaining water levels over 0.5 m is effective in controlling spread of cattail.

Natural Disturbances

Severe flooding, hurricanes, and fire are the major natural disturbances that greatly affect wetlands. Although wetland plant and animal communities are adapted to each of these disturbances, events of exceptional magnitude and duration, or that occur during unusual times of the year, can have profound effects. A serious concern following any of these severe events is the spread of invasive species.

During the 1993 flooding of the Mississippi River, submerged aquatic, emergent wetland, and floodplain species

were adversely affected by extreme sediment deposition, uprooting due to wave action, and probably increased inputs of agricultural chemicals. Recolonization of open spaces left by plant mortality can happen quickly by germination of local or upstream plant propagules.

Hurricanes especially affect the mangrove forests of the Gulf of Mexico and Caribbean, and the deep-water and alluvial swamps of the southern United States. These coastal forests, where many species have shallow root systems, are often subjected to the highest winds and succumb to windthrow. Trees that are especially resistant to windthrow (e.g., *Taxodium distichum*) may lose most of their crown but are able to reestablish a new canopy quickly by extensive sprouting along the bole. Seedling regeneration is generally higher after such disturbances because of increased light and microsite availability. Storm surges of saltwater occasionally cause greater damage than high winds to species intolerant of high salinity.

Forested wetlands on substantial peat deposits, such as the black spruce (*Picea mariana*) and tamarack (*Larix laricina*) swamps of the boreal forest and baldcypress swamps of the southeastern United States, have naturally burned during periods of extreme drought. In northern climates, fires can convert the forest to a more open peatland. In the southeastern swamps (e.g., Okeefenokee Swamp), fires can convert forested wetlands to prairie-like, tree-less wetlands. Fire can favor the regeneration of some tree species, like *Chamaecyparis thyoides* (Atlantic white-cedar), which regenerate best under full sunlight conditions on saturated peat. In the Everglades of southern Florida, open sawgrass marshes naturally burned every 1 to 5 years, ignited by lightning strikes from May to October when water levels are highest and substrates are saturated. However, human-set fires are most common from November to May when soils can be dry enough to ignite. These fires, to which the vegetation is not well adapted, can cause substantial ecological damage.

Restoring and Maintaining Wetland Diversity

Because of extensive loss and degradation of wetlands throughout the world, and continuing loss and degradation in much of the world, maintaining wetland diversity will require a strategy that includes restoration. The ultimate goal in any specific wetland restoration project is to have a self-sustaining, functioning ecosystem. The following discussion focuses on techniques to achieve this goal. However, in terms of restoring wetland diversity, the goal must be a broader one—best addressed at the landscape, regional, and continental scale—to restore the structure, function, and self-sustaining properties of a wide diversity of wetland types. Without attention to restoration of the full complement of wetland types, wetland diversity cannot be restored at any but the smallest scales.

Restoring self-sustaining wetland ecosystems initially, and at later times, may require various engineering, horticultural, and wildlife management activities (National Research Council, 1992). The intensity of these activities depends on whether the site was initially an upland (thus requiring wetland "creation"), a wetland that has been drastically disturbed (e.g., through conversion to agricultural crop production), or disturbed to lesser degrees. In some cases, a wetland may have reached a successional stage that does not support a species or group of species of concern, and manipulation is required to maintain these species. Nontidal emergent wetlands are generally easiest to restore. Long-term monitoring of site hydrology and vegetation is required to determine if and when project objectives are not being met.

Because wetlands serve many functions, and seldom can all functions be restored in a single site, restoration objectives must be clearly defined for every project. Restoring wetlands as habitat for rare and uncommon species, or for overall biological diversity, especially requires clear statements of objectives, as well as thorough knowledge of the ecology of the species of concern. Wetlands that could be correctly described as functioning wetlands have failed to attract the species for which they were restored. Consider the restoration of a bottomland hardwood forest. The restoration could be viewed as successful if a certain percentage of planted oak (*Quercus*) species and individuals were to become established after a given period of time. However, such a planting would be a failure in terms of restoring the diversity of neo-tropical migratory birds, which would fail to use the site because they require a more complex forest structure. In general, a higher overall plant and animal diversity is achieved by planting an array of fast-and slow-growing plant species, and where appropriate a mix of woody and herbaceous species tolerant of the range of hydrological and chemical conditions at a site.

The first step to restoring wetland plant composition, structure, and function is to ensure a range of hydrological conditions by implementing various techniques. Depending on the existing condition of the site and restoration goals, these techniques may include reestablishing stream flow or tidal fluctuations, restoring flood regimes, halting drainage, and reestablishing topography and microtopography. These conditions can be attained by excavating basins or channels, constructing dikes, grading an undulating topography, installing water control structures, plugging ditches, and removing drainage tile lines. If the site is to be used for the reintroduction of rare species, there are additional considerations, especially genetic, political, and legal issues.

Once a range of hydrological conditions is established, plant species best adapted to each specific hydrological condition can be selected. Many wetland restorations fail because the relatively few plant species selected grow poorly or die because conditions are too wet or dry for too long. If the goal of a particular restoration is to restore functions such as flood control or nutrient retention, then relatively few plant species need to be planted. If the goal of a project is to restore the natural heritage or educational values of a wetland, or to reestablish the compositional and structural complexity of highly diverse wetlands, then many plant species should be established.

Sources of native trees, shrubs, sedges, grasses, and herbaceous species include plant nurseries and other wetlands, especially those that are planned for future, permitted alteration. Seeds of many wetland species can be collected and grown for future transplanting or direct seeding. Some woody species can be established from stem cuttings. Many herbaceous species can be propagated from divisions off the parent. Spreading soil collected from a donor wetland, especially

those planned for future alteration, will provide the greatest diversity of plant and animal organisms. Numerous woody and herbaceous plant species can arise from transplanted soil, via whole plants, seeds, roots, rhizomes, and stolons. Including leaf litter, detritus, and, for forested wetlands, large amounts of coarse woody debris are beneficial.

Herbivores cause many wetland restoration projects to fail, directly (by feeding) and indirectly (by burrowing, by dam building). Invasive species, such as *Lythrum salicaria*, *Phragmites australis*, and *Tamarix* spp., also must be controlled if plant and animal diversity are desired.

Understanding the ecological factors that control the diversity of animals in wetlands is key to altering these factors to restore, enhance, or create wetlands for the benefit of wetland fauna. Because hydrology underpins so much of wetland ecology, manipulation of wetland hydrology through water-level regulation is the most common and cost-effective way to manage wetland habitats for wetland fauna. More specifically, water-control structures can be used to flood or drain wetlands and thereby alter plant communities and the habitats available for wildlife. By drawing down water levels, a germination phase can be produced, which can be followed by gradual reflooding once plant communities become established. Timing, duration, and degree of drawdown (for example, shallow, growing season drawdowns versus complete overwinter drawdowns) influence subsequent plant species composition and the types of wildlife later attracted. Several years of stable water levels of moderate depth following drawdown are often required to establish the submerged plant communities that are important to many wetland animals (invertebrates, ducks, fish). Manipulation of wetlands to produce early stages of plant succession can create a diversity of habitat niches for wetland animals, particularly if practiced within a wetland complex in which management of different units is staggered for different successional stages. This practice permits the wetland fauna, elements of which can be quite mobile, to track habitat conditions over time and persist over the long-term within the same local area. Manipulation of wetland hydrology also has been used to manipulate salinity in coastal areas by blocking natural drainages, thereby permitting the fresh water that accumulates to leach out salt. The resultant shift in plant communities to more salt-intolerant species also changes wildlife communities.

In addition to water-level manipulation, a number of artificial procedures can be used to modify wetlands to enhance wildlife habitats. These include creation of openings in dense emergent vegetation through cutting, application of herbicides or, more permanently, by blasting. Planting of select forage species is sometimes attempted but is usually expensive and rarely successful. Provision of artificial nest sites for select species, especially ducks, has been one of the most common and visible forms of wetland management to benefit wildlife. Artificial nesting and loafing sites can be constructed for birds. Large, whole tree boles, including partially hollowed-out trees, can be placed within or adjacent to the restoration site. While perhaps aesthetically pleasing, the overall contribution of such efforts to boost local populations is at best modest given the small fraction of regional populations that can be supported by such structures. These artificial procedures, in general, are expensive and time-consuming and should be considered a minor complement to a larger strategy of natural management that uses hydrological manipulation to produce habitat changes over large areas in a cost-effective manner.

The tradeoffs between community types must be articulated and considered in management and planning. For example, flooding bogs and meadows to produce marshes, a not uncommon occurrence in North America, entails losses of certain species, many rare or unusual, and gains of others, many common and sought after by recreational users. In general, maintaining wetlands in a productive and natural state that meets the needs of the entire wetland fauna is more likely to meet diverse public needs than is species-specific management (e.g., for waterfowl only).

Conclusions

Despite lack of systematic comparisons, the existing scientific literature on wetland ecosystems is unambiguous in conveying the high level of diversity supported by wetlands. The source of this high diversity lies in the exceptionally large number of different types of wetlands that occur worldwide. Because wetlands occur on every continent except Antarctica, in every climatic region, in most biogeographic regions of the globe, and in a wide array of geological and topographic settings, the number of different types of wetlands created by the myriad combinations of these factors is very large and has yet to be catalogued. The extraordinary richness of plant and animal species that depend on wetlands arises from this diversity of types. Relative to the area they occupy, wetlands support a disproportionately large fraction of the world's rare, endangered, and threatened plant and animal species. Maintaining the high diversity of wetland species means maintaining a high diversity of wetland types.

Glossary

Density dependence Change in the birth and death rate of a population as a result of changes in population density; usually in the form of increased mortality rate and decreased fecundity as density increases.
Focal species A species that can be monitored and managed to maintain the integrity of the ecological system of which they are a part.
Information-theoretic approach A method of comparing between multiple competing models explaining a phenomenon based on the information lost (estimated distance from the truth) by each model.
Intermediate disturbance hypothesis A hypothesis claiming that some level of disturbance is necessary to maintain biodiversity.
Minimum viable population (MVP) A method for assessing the minimum size a population must be, to bring its extinction over a given time span to below a predetermined level.
Multimodel inference A method used to assess the uncertainty in model selection by calculating likelihoods among multiple competing hypotheses (models), most commonly based on Akaike's Information Criteria (AIC).
Population viability analysis (PVA) A method of assessing the probability of extinction for a given population within a specified time span.
Stochastic processes Processes that affect the dynamics of a population through random chance alone.
Sustained yield The removal of a constant number of animals from a wild population that can be maintained through time while keeping the population at a predetermined size.

Introduction

Although the term wildlife can be expanded to include all living organisms, the science of wildlife management, as an academic program offered and taught in universities and as written in textbooks, generally refers only to vertebrates.

Five major goals of wildlife management can be recognized.

1. Maximizing harvest/yield over time.
2. Maintaining population levels to support harvest and sport hunting.
3. Preventing extinction and increasing population survival probability.
4. Maintaining and managing the integrity of ecosystems and landscapes of which wildlife populations are a part.
5. Controlling wildlife to minimize damage to human crops and assets caused by wild populations or to return the ecosystem to some predetermined state.

As a science, wildlife management relies heavily on the understanding of ecological theory and processes, but differs from the science of ecology in its research objectives. Ecological research is targeted at formulating new hypotheses and providing the data to support or reject them. Thus, the species or setting selected to perform the research is that which is best suited to test a specific ecological theory. In contrast, research in wildlife is often dictated by real needs of specific problem-species or specific environments. The management of wild populations requires four processes: assessing the problem and defining the management objectives for the target population, monitoring and analyzing the ecology of the target population, formulating and implementing management actions based on the identified problems and ecology of the target population, and evaluating the implemented methodology. These processes can be carried out on a local or global scale (e.g., migratory waterfowl). In addition, because wildlife management is an applied science, involving what is often a national asset, public opinion strongly influences its goals. Thus, education, law enforcement, and public relations are also legitimate and appropriate aspects of wildlife management.

Harvest and the Concept of Sustained Yield

The science and profession of wildlife management have evolved over time based on perceived needs and ecological understanding. Originally, the field of wildlife management addressed only game species and harvest issues, recognizing wildlife as a crop that is a product of the land. The realizations that populations may go extinct due to overharvesting and past harvest rates affect the future performance of wild populations were the main forces driving the development of the science (Leopold, 1933). The recognition that populations can be overharvested is not new (a review of past examples of game management can be found in Aldo Leopold's book *Game Management*). As far back as biblical times, harvesting wildlife intelligently was considered important (Deuteronomy 22:6). According to Marco Polo's writings, Kublai Khan imposed hunting regulations throughout his Mongol Empire. The first refuge in the modern western world was established

by the British Parliament in 1869. However, the formulation of wildlife management as a quantitative science occurred only during the early part of twentieth century, driven mostly by the concept of "sustained yield" and its maximization (e.g., maximum sustained yield (MSY)). Leopold's *Game Management* was a keystone to this process, as was President Roosevelt's doctrine of conservation.

Sustained yield refers to a constant level of harvest that when applied, will allow the harvested population to stabilize at a given size. This can be achieved by removing an amount equal to the population's rate of increase. In the absence of limiting factors, the rate of increase of a population should remain unchanged, and, therefore, absolute growth will increase with population size (more animals have more offspring). However, populations do not grow indefinitely, which suggests that at some point, the population rate of increase begins to decline as the population increases. This density-dependent response is due to a decline in the amount of resources available per individual, which causes a subsequent reduction in reproductive success and increased mortality. The classic logistic growth equation, introduced by Verhulst in 1838, describes the growth curve of such a population, depicting an S-shaped curve of population size against time (**Figure 1a**). The rate of increase of the population at time t is the first derivative (dN/dt) and is given by

$$\frac{dN}{dt} = r_{\max} N\left(1 - \frac{N}{K}\right) \qquad (1)$$

where N is the population size at time t, $r_{\max}$ is the maximum growth rate per individual when resources are not limiting, and K is the maximum size of the population that can be supported over time in a particular environment (K is often termed "carrying capacity"). As can be clearly seen, there are two cases when population growth is 0; when $N = 0$ and when $K = N$. Thus a sustained yield requires that the population be kept below K. Between $N = 0$ and $N = K$, growth rate initially increases with population size and then decreases (**Figure 1b**). Each point on this curve represents the sustained yield for a given population size, and the highest point is the MSY.

We calculate MSY by finding the maximum value of dN/dt. This can be done analytically by taking the second derivative of the equation depicting the growth curve of the population and equating it to 0. In the case of the logistic equation,

$$\frac{d(dN/dt)}{dN} = r_{\max}\left(1 - 2\frac{N}{K}\right) = 0 \qquad (2)$$

This equation equals 0 when $r_{\max} = 0$ (which is meaningless) or when $2\frac{N}{K} = 1$. Rearranging the latter, we find that $N = \frac{K}{2}$; that is, the population grows the fastest when at $\frac{1}{2}K$. To find the rate of increase at that point, we simply substitute $\frac{1}{2}K$ for N in equation (1) and find that the maximum growth rate and, therefore, MSY, is $r_{\max}\frac{K}{4}$.

Note that except for the point of MSY, a given yield (growth rate) can be achieved at two different population sizes, one on either side of MSY$\left(\frac{K}{2}\right)$ – the upper and lower sustained yields. Thus it appears that one may achieve the same level of sustained yield with a small population as with a large one. However, the two points differ considerably in terms of stability. The points to the right of MSY are stable because moderate overharvesting will increase the growth rate of the population, thus compensating for the excessive harvest (and vice versa). In contrast, the points to the left of MSY are unstable because overharvesting will cause a decrease in the rate of increase. As a result, the next harvest will further decrease the population and rate of increase and so on. Initially the impact may appear minor, but this "snowballing" effect can very quickly lead to the demise of the population.

Clearly, real populations do not behave deterministically nor does their density-dependent response follow that of the logistic model. Density-dependent responses may vary depending on the species and environment, skewing the dN/dt curve; the age structure of the population must be considered; the environment (carrying capacity) constantly changes; other species (predators, competitors, etc.) interact with the population; and hunters may select for specific animal traits (sex, age group, size, etc.). Thus, much of the research on harvested populations has been directed at developing more sophisticated models with better predictive capabilities and estimating the parameters needed for them (Getz and Haight, 1989; Saether, 2001).

Although many advances have been made in this field, to date, harvest strategies in many places around the world are still implemented on a trial-and-error basis trying to just maintain a level that will support hunting and produce revenue. However, even under such protocol, harvest theory has made an important contribution in demonstrating that uncontrolled harvest can very quickly lead to the demise of populations. Furthermore, while the logic of a sustained yield set somewhat above MSY is obvious, nonecological factors may have a strong influence on harvest policy. In many

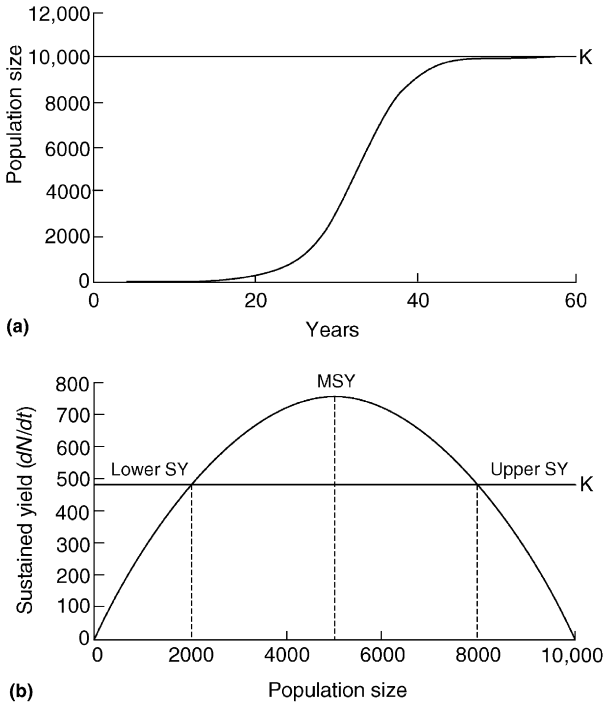

Figure 1 The logistic population growth curve as a function of time (a) and sustained yield as a function of population size (b).

species, the long-term monetary income from a sustained yield may be less than the yield offered by the economic market on regular investments (Clark, 1976). In other words, economically, a greater profit can be realized by selling licenses to hunt the entire population and investing the profits than by limiting the number of licenses to a sustained yield that will ensure the continued existence of the population. Thus, in recent years considerable effort has been directed at assessing the economic value of wildlife for nonconsumptive uses such as tourism and conservation (Fennell, 2008).

Endangered Species and Reducing the Risk of Extinction

With the biodiversity crisis coming into focus during the second half of the twentieth century, the science of conservation began to evolve. Initially, conservation to preserve an endangered species and wildlife management were treated as separate sciences. Eventually, the sciences merged in the area where they overlap (wildlife), and managing wildlife populations for conservation became an integral part of wildlife management. Topics such as management for recovery and sustainability, the dynamics of small population (especially as impacted by demographic, genetic, and stochastic environmental processes), fragmentation, and the importance of populations to the integrity of the ecosystem and biodiversity became a central focus of wildlife management. In terms of management for conservation, Caughley and Gunn (1996) recognized two central paradigms: the small population paradigm and the declining population paradigm.

The sensitivity of small wildlife populations to extinction was first recognized and expressed in 1938 in a book written by the famous American ecologist Allee. In his book (Allee, 1938), Allee writes: "The general conclusion seems to be that different species have different minimum populations below which the species cannot go with safety, and that in some instances this is considerably above the theoretical minimum of one pair." Four types of stochastic processes (Shaffer, 1981) play an important role in the dynamics of small populations and contribute to their increased risk of extinction: demographic stochasticity, genetic stochasticity (including loss of genetic variance and inbreeding depression), environmental stochasticity, and catastrophes.

The accelerated loss and fragmentation of wildlife habitat during the second half of the twentieth century restricted many wildlife populations and required that management steps be taken to minimize these stochastic effects. The size of refuges and other areas set aside for conserving wild populations must be large enough to support a population equal to or larger than the minimum viable population (MVP) (Belovsky, 1987). Corridors connecting small populations are currently considered important (Bennett, 1999), but their effectiveness has not yet been fully demonstrated. Where the establishment of corridors is not feasible, translocation has been implemented. For instance, in South Africa, mountain zebras are translocated by airlift between isolated populations. Habitat improvement and resource supply during limiting periods of harsh environmental conditions are also being used to minimize population declines and reduce the impact of stochastic processes and risk of extinction.

The management of declining species requires that the cause of decline be identified and managed directly or indirectly. Human-related decline of wildlife populations in the twentieth century can be attributed to three main factors: overharvesting, loss and fragmentation of habitat, and the introduction of alien species. With the improved control of harvest by science and legislation, loss of habitat and fragmentation became the major causes of wildlife population declines. This process has highlighted the importance of considering space in wildlife management. Management efforts have been concentrated on land allocation for conserving wildlife and securing refuges and linkages (corridors) between patches (fragments) of adequate habitat. Roads and fencing are some of the major causes of fragmentation, and special overpasses, underpasses, and gates have been developed to ensure wildlife movement.

Managing Wildlife for Conserving the Integrity of Ecosystems and Landscapes

Wildlife populations are important for maintaining biodiversity in the system of which they are a part. Many wild populations are critical for the functioning of the entire community. Beavers (*Castor canadensis*) are a classic example of how a single species engineers change in the ecosystem beneficial to many other species. Prairie dogs (Cynomys spp.) are another example. Thus, in many instances, populations are managed in order to sustain species richness of the ecosystem of which they are a part. For example, research has shown that both overgrazing and undergrazing will reduce plant species richness. This is known as the intermediate disturbance hypothesis (Connell, 1978). In certain cases, herbivore populations are managed to maintain the diversity of the plant community. Elk (*Cervus elaphus*) populations were regularly controlled to maintain the existing landscape in Yellowstone National Park. Wolves (*Canis lupus*) were reintroduced (Fritts and Carbyn, 1995) into Yellowstone with the hope that they would control the elk population thus restoring cottonwood stands along the river-banks. The control, however, was not manifested by direct predation, but rather by changes in the behavior of elk that avoided the riverbanks due to the increased risk imposed by the newly present wolves (Ripple and Beschta, 2004).

The use of focal species as a tool to manage ecosystems gained popularity in the 1990s but has waned in the past decade. The underlying assumption is that by managing the focal species, the entire system, or a significant part of it, can be secured. Indicator, keystone, and umbrella species are the main types that have been suggested as focal species through which systems can be monitored, conserved, or managed.

Indicator species are species that testify to the well-being (health) of the entire ecosystem. These species are the first to respond to deterioration of the ecosystem, since they are more sensitive. By monitoring and managing the indicator species population only we can estimate and protect the welfare of the entire ecosystem. We assume that as long as the status of the

indicator species is satisfactory, the entire system is operating adequately.

Keystone species are species that play an important role in the ecosystem. These may be animals that hold most of the biomass in the ecosystem or that influence many of the other species or functions of the ecosystem. In this way, if the population of a keystone species is removed from the ecosystem, the ecosystem changes dramatically. Therefore, by managing only the population of keystone species, we are managing most of the ecosystem. In recent years, species that modify the environment (termed "ecosystem engineers") have become a point of interest (VanNimwegen *et al.*, 2008).

Umbrella species are species that require a large area containing many types of habitats to sustain a viable population. Often these are large-bodied homeotherms with large home ranges. By securing a tract of land that is large enough to sustain a viable population of these species, many others will come under the same protection. The focus here is on leaving enough area for the umbrella species and other members of the ecosystem, but there are no direct management implications for this approach.

Control of Wildlife

The everexpanding human population ensures that human–wildlife conflicts will continue. Most of these conflicts are within the realm of damage to crops, equipment, and other assets. Thus, a major component of wildlife management is wildlife control. A good example is managing habitats around airports to reduce gull activity near runways that endangers aircraft during takeoff. Often, damage caused by wildlife is a result of human manipulation of the environment, such as outbreaks of herbivores following the eradication of predators and high concentration of canids around human waste sites leading to outbreak of rabies. Wildlife management strives to implement control measures in a manner enabling the other goals of wildlife management (sustained yield or maintaining biodiversity) to be met.

The four processes necessary for wildlife management generally apply to wildlife damage control, with some differences. These processes are the following: (1) Defining the problem. The species causing the damage must be identified, the type of damage determined, and extent of the damage evaluated. (2) Knowledge of the general ecology, behavior, and dynamics of the species causing the damage must be obtained and evaluated with special regard to its response to various control techniques. (3) The combination of (1) and (2) defines the methods that are feasible and economical to control the damage. (4) The methodology used must be evaluated. Unless the cost of control is less than the losses due to the damage, management should not be implemented.

Wildlife Management Techniques

Because wildlife management is an applied science, methods and techniques for both research and implementation are important. As a result, a considerable amount of research has been directed at developing, assessing, and improving techniques. Techniques for managing wildlife are aimed at studying, reducing, increasing, or maintaining the population at its current level while securing its integrity (i.e., preventing loss of genetic diversity, enhancing long-term survival, preventing epizootics, etc.) and the integrity of its ecosystem. The techniques can be classified generally into two categories.

1. Applied techniques for manipulating populations by impacting survival, reproductive success, or distribution.
2. Techniques for studying, analyzing, and assessing population.

Many of the more common techniques are published in a series of *Wildlife Techniques Manuals* published by The Wildlife Society. The first of this series, edited by Mosby, was published in 1960. The most recent issue (the 6th edn.) was published in 2005 and edited by Braun. The manual covers five main topics: teaching and communication skills, study design and analytical techniques, investigational techniques, managing populations, and habitat management.

Applied Techniques for Managing Wildlife

Applied techniques may be resource (habitat) manipulation, mechanical, behavioral, immunization and immunocontraception, biological, and direct population control.

Habitat and community manipulation: This refers to managing target species by impacting important resources and other species that interact with them (i.e., habitat manipulation, or impacting predator–prey relationships and competing species, and species that are ecosystem engineers). By controlling key elements that affect the species abundance (water, shelter, predators, etc.), it is possible to manipulate its density and distribution. The increase in computer power enabled the use of spatially explicit models and Geographic Information Systems techniques to project the impacts of various habitat manipulations (Verner *et al.*, 1986).

Mechanical: The simplest and most successful method of controlling wildlife damage is exclusion by fencing. The advantages of fencing are that it is relatively fail-proof and nonlethal. However, it is expensive and labor intensive, demanding constant upkeep. Furthermore, fencing large tracts of land is a major cause of fragmentation.

Behavioral: These are modern forms of scarecrows that operate on the animal's senses and are, therefore, acoustic, olfactory, or visual. A good example of visual repellents, other than the classic scarecrow, is the silhouettes of birds of prey that are placed on large glass windows to prevent other birds from slamming into them. Examples of acoustic deterrents are gas cannons that produce explosions at irregular time lapses or recordings of alarm calls of other animals. Ultrasonic deterrents work by using sounds at a high decibel level (above 120 dB), outside the range of human hearing, to cause a painful stimulus to animals with sensitive hearing, such as canids. Olfactory repellents are chemical compounds. Two types of chemical compounds can repel animals: (1) compounds that link a food source with an induced sickness through a behavioral process called conditioned taste aversion; and (2) compounds that repel through the unpleasant stimuli of the nervous system. The first type are properly

referred to as aversive agents, while the second type are true sensory repellents.

Immunization and immunocontraception: These techniques require the administration of a vaccine either directly, by capturing and injecting, or indirectly, by oral administration with bait. A major advancement in wildlife management in the past decade is the control of rabies by oral immunization. Immunocontraception is a very attractive method of control because it is potentially highly species specific, but it so far has had limited success.

Biological: Biological control has been mostly effective against insects. There are only a few cases in which biological control was effectively applied to wildlife. Of these, the introduction of *Myxoma* virus to control rabbits introduced into Australia is the most famous. Although complete eradication was not achieved, the virus now holds the rabbit population at 20% of its original size.

Direct population control: Direct population control refers to the removal (harvesting) or addition (reintroduction and translocation) of animals. Removal is usually used when the animal is a game species and can also be controlled by hunting license quotas. Its main advantages are that it is species specific, the number of animals removed can be closely controlled, and it has limited impact on the environment. Reintroductions and translocations are important methods for enhancing the viability of existing populations and reducing the species risk of extinction.

Studying, Analyzing, and Population-Assessing Techniques

A major prerequisite of sound management is the accurate estimates of population size and dynamics, and determination of how these are influenced by other factors. Consequently, a significant part of wildlife science today is directed at the development and improvement of estimation techniques for assessing population density, survival, reproduction success, occupancy, well-being, age structure, density-dependent responses, and interspecific interactions. Such data are the basic requirements for estimating sustainable harvest quotas in different and variable environments and assessing extinction probability and other risks.

Rigorous statistical methods for assessing density and survival based on maximum likelihood estimation techniques, are continuously being refined. These methods evolved from a landmark paper (Seber, 1970) on estimating survival from the recovery of dead animals, and the insight of David R. Anderson of the US Fish and Wildlife Service who recognized the potential of Seber's work. Computer software such as DISTANCE, SURVIV, ESTIMATE, JOLLY, BROWNIE, and more recently MARK, were developed specifically for wildlife research and management (Dinsmore and Johnson, 2005).

Research and management of wildlife are carried out over large geographic areas, often with limited access and visibility. Considerable effort has been directed toward developing remote data collection techniques using indirect methods of assessing population condition and nutrition by using individual animal physiological indicators (Servello *et al.*, 2005).

Methods for assessing the viability of small populations (population and habitat viability analysis, (PHVA)) and estimating the minimum population size necessary to ensure its long-term existence (MVP) have been developed based on stochastic theory (Burgman *et al.*, 1993). Commercial software such as RAMAS and Vortex are available for PHVA and MVP analysis; however, in most cases and due to the detailed knowledge required, the data are insufficient for a reliable analysis.

Clearly the greatest change in the analysis of data from wild populations in the past decade is the use of the Kullback-Leibler information-theoretic approach and multimodel inference (as opposed to the standard Popperian approach). This approach was integrated into the field of wildlife management and evolved within it, driven by the need to deal with multiple potential predictor variables (Burnham and Anderson, 2002). The approach has consequently filtered into the basic-ecology literature and reflects a paradigm shift in this and related fields.

Glossary

Chaetae Bristles composed of chitin cylinders glued together by scleroprotein emerging from parapodia or the body wall in many annelids, including most polychaetes and in the oligochaet families of the clitellates, but present in most of all major annelid taxa.

Nuchal organ Sensory organs with nerves coming from the posterior part of the brain or from the nerve ring, usually present as ciliated pits or short ridges at the posterior end of the prostomium, present in most polychaetes species, also present in the sipunculans.

Parapodium Segmentally arranged outpockets from the body wall, usually divided into two branches (rami), the dorsal notopodium and the ventral neuropodium; present in most polychaete species, but extremely variably developed and sometimes entirely absent.

Peristomium Region around the mouth of the larvae; if distinct in adults may carry peristomial cirri.

Prostomium Morphologically anteriormost part of the body; may carry antennae and eyes and carry at least part of the brain.

Segment In annelids a section of body set off from the rest of the body by septae at both ends; containing a separate part of the secondary body cavity (coelom) with paired ventral ganglia, and usually nephridia, gonads, transverse muscles and segmental blood vessels carrying externally parapodia with chaetae and gills in most polychaetes, chaetae in oligochaetes. Distinct segments present in posterior end of siboglinids (pogonophorans and vestimentiferans), indistinct in most other annelids.

Trochophore Larva characteristic especially of annelids and mollusks, consisting of an episphere, a ciliated girdle around the middle called the prototroch, and the hyposphere. In feeding trochophores the mouth is located behind the prototroch and the anus is terminal, usually surrounded by a second ciliated band, called the telotroch. Segmentation takes place between the prototroch and the telotroch and is initiated immediately in front of the telotroch.

Annelida

Traditionally the phylum Annelida consisted of three classes: Polychaeta, Oligochaeta and Hirudinea. The Hirudinea were shown to be derived from one of the oligochaeta groups, so the two groups are now fused to Clitellata. The clitellates have been shown to be closely linked to one of the polychaete groups, so Polychaeta is now considered a paraphyletic group in relation to the clitellates.

Two small, mainly deep-water phyla, Vestimentifera and Pogonophora have been shown to be a single group, and to belong to a single family, Siboglinidae, a sister taxon to the sabellid polychaetes; thus these two phyla are now considered annelids belonging to one of the polychaete groups.

Recently the spoon worms, phylum Echiura, have been linked directly to the annelids, probably most closely related to the clitellates. Finally, the peanut worms, phylum Sipuncula, have been shown to be related to the annelids, but the position is still debated.

One group, Myzostomida, parasitic on echinoderms, was considered a member of the Polychaeta; they were then removed from the Annelida and associated with the Platyhelminthes, but they are now back among the annelid-related groups, in a somewhat uncertain position.

The evidence for this reorganization of many of the worm-like phyla comes only in part from morphology or embryology, the most convincing evidence has been supplied by molecular genetics.

Polychaeta is a commonly encountered group of annelids (segmented worms) best represented in the marine environment, although several species are present in freshwater and a few are known from moist soil on land. The Polychaeta, the many-bristled worms, include about 15,000 described species. Estimates of the total number of species varies, but judging from the rates of description of new species it is likely that more than 20,000 species will eventually be recognized, based on morphological characters in addition to the study of all genetically fixed properties of the worms. No single feature can be used to diagnose the taxon uniquely; until recently the presence of the nuchal organs were considered such a feature, but even this structure is missing in several polychaetes and present in Sipuncula.

Clitellata contains the earth worms and their aquatic relatives and the leeches. The clitellates evolved from the polychaetes, but the exact relationship has not yet been diagnosed.

Morphology

This section is based mainly on the polychaetes, since these are perhaps the most complex of the annelids.

The annelids are composed of three body regions, derived from regions present in the larvae. In the polychaetes the presegmental prostomium and peristomium are followed by a segmented body and a postsegmental pygidium, which carries the anus. Most polychaetes are less than 100 mm in length

 http://dx.doi.org/10.1016/B978-0-12-384719-5.00170-2

with 100 or fewer segments; many are very small, with as few as 10 segments, and are adapted to life between sand grains in sandy beaches. Some species may become very large with 2–3000 segments and lengths between 1 and 3 m; the longest recorded specimen was more than 6 m long when collected in Port Jackson, Australia. These very large worms may be as old as 50–100 years, but the documentation for this is rather poor. In general, small species are short lived compared to larger relatives. Perhaps most polychaetes live 12–18 months, while others go through three or four generations in a year. The general body shapes may be earthworm-like with cylindrical bodies and very little in the way of external appendages, but more usually the protruding parapodia and chaetae make the worms appear ragged. The ventral side may be flattened with two longitudinal ridges on either side of the mid ventral nerve chord; the dorsal side is usually convex. This description fits best for mid-sized free-living worms; the tubicolous worms are often cylindrical with inconspicuous parapodia, the very small species are often slender and the parasitic species may be flattened and disc-shaped.

Of the clitellates the oligochaetes are slender; most aquatic species are small, the terrestrial ones may be very large, such as the giant earthworms present in Australia. The leeches are usually flattened and have suckers developed at one or both ends of the body.

The echiurans are often large, rounded or sausage shaped, without any visible segmentation and with a pair of, or sometimes more, hooks just behind the mouth; the prostomium is spoon shaped or sometimes extremely elongated T-shaped.

The sipunculans are often more or less peanut shaped (hence the common name) when the anterior end is retracted; when this end is extended they become elongated drop shaped with a crown of feeding appendages anteriorly.

Head

The head consists of the prostomium and peristomium in the adults, but one or more of the first segments may be fused to this structure (see **Figures 1–3**). The prostomial part may carry antennae and eyes, and the fused anterior segments may have a pair of tentacular cirri per fused segment; these cirri are the dorsal and ventral cirri of each segment participating in the head structure. In Canalipalpata the head end can be complex and the number of segments included in the head may be difficult to count. Some of these worms may have a tentacular crown (e.g., the sabellids and serpulids) or a very large number of antennae (e.g., the terebellids). Certain polychaetes lack anterior appendages entirely (e.g., the capitellids and maldanids).

In clitellates the head consists of the prostomium and peristomium and lacks appendages. In the echiurans the prostomium is most often short and spoon shaped, but may be extremely elongated and distally T-shaped. In the sipunculans the prostomium is a rounded lobe when distinct and the peristomium consists of branching groups of feeding appendages.

Segments

Segments are always added just in front of the pygidium, that is, from the posterior end of the segmented body. They are often first seen as low ridges just in front of the pygidium; parapodia, chaetae and other externally obvious structures are differentiated as more segments are added and, as a consequence, each segment no longer has the position of the last segment. The total number of segments may be fixed and limited (e.g., 20, 25, etc., in certain polynoids, maldanids and opheliids). In many species the number of segments varies with relatively narrow ranges; for example, many neridid species have 80–120 segments. Some species have an unlimited number of segments and the worm keeps on adding segments throughout life. Normally each segment has a pair of parapodia (see **Figure 4**). In many species the parapodia are poorly developed and marked only by the position of the chaetae; in other taxa the parapodia are complex structures with a variety of lobes and lamellae. In well-developed parapodia the two rami often differ. The notopodial are smaller (or shorter) than the neuropodia in many species; when they are completely missing the parapodia are called uniramous. In the identificatory literature a number of terms (e.g., sequiramous) are used to characterize the level of reduction of the notopodia. These terms are used inconsistently and it is better to specify the structure observed than to apply a poorly understood term. When the parapodial are best developed each ramus has a chaetal lobe supporting one or more bundles (or fascicles) of chaetae and pre and postchaetal lamellae covering the bases of the emerging chaetae. The chaetal lobe is supported by one or more acicula in many species. A dorsal cirrus is found on the dorsal edge of the notopodium or on the adjacent body wall and a ventral cirrus is along the ventral edge of the neuropodium; both cirri are mainly sensory structures. In addition to the pre and postchaetal lamellae various other lamellar or finger-shaped structures may be associated with each ramus. A complex terminology is associated with shape and position of each structure. Clitellates have distinct segments, often subdivided into two or more rings, but lack parapodia. In echiurans, larvae may have more or less distinct internal segmentation distinct mainly as groups of muscles; the sipunculans lack distinct segmentation, note however, that the sipunculans have the body cavity separated into an anterior and posterior cavity organized so that the eversion of the anterior end is supported from musculature in the anterior cavity.

The Pygidium

The pygidium may be a rounded or tapering simple structure with the anus opening either dorsally or terminally, but frequently it carries anal (or pygidial) cirri. Commonly one or two pairs of cirri are present, but in some taxa it may be ornamented with numerous cirri or flattened lamelliae (e.g., maldanids), and in the opheliids it may have an open hood with many papillae, both inside the hood and along the margin.

In the sipunculans the digestive tract is U-shaped and as a consequence the anus opens at the base of the anterior introvert.

Chaetae

The chaetae, the bristles, may be in bundles, however, in most cases the ''bundles'' consist of two or more short, oblique rows

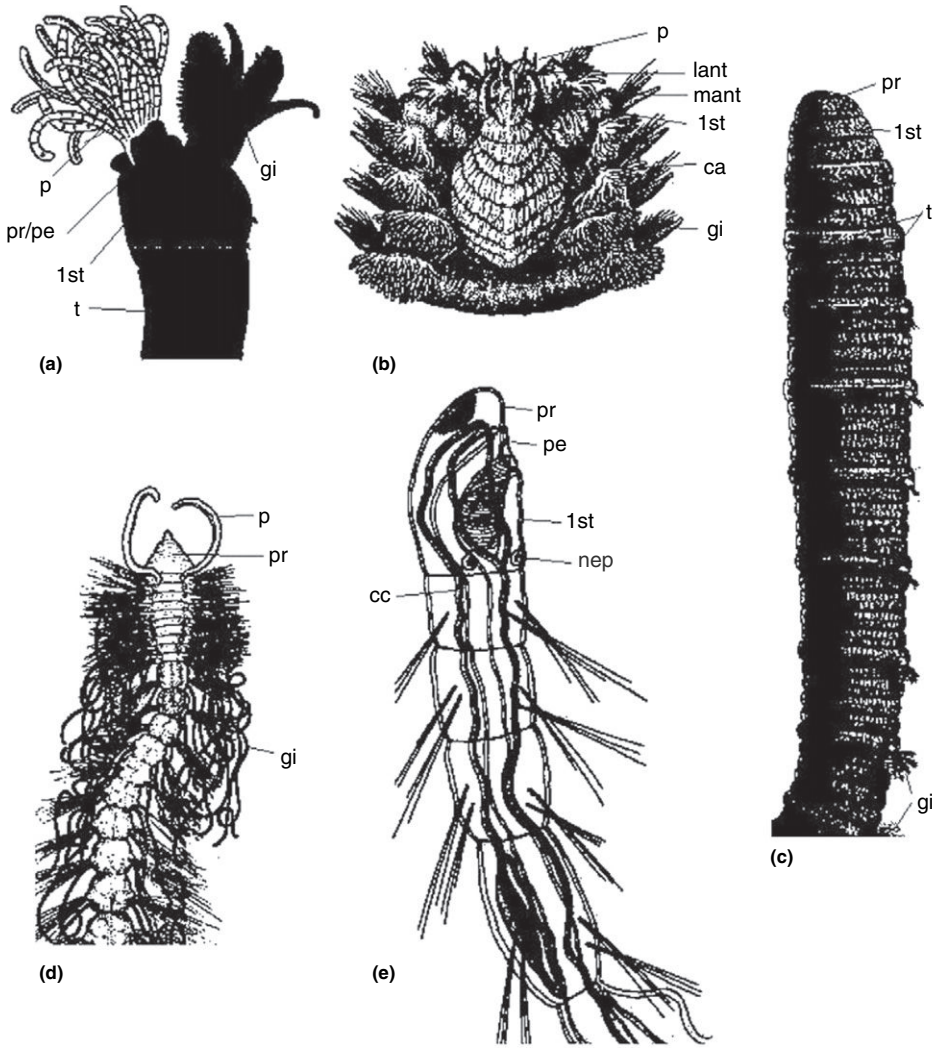

Figure 1 Polychaete anterior ends. (a) Ampharetid, lateral view. (b) Amphinomid, dorsal view. (c) Arenicolid, lateral view. (d) Cirratulid, dorsal view. (e) Ctenodrilid, lateral view. Modified from Rouse GW and Fauchald K (1997) Cladistics and polychaetes. *Zoologica Scripta* 26(2): 139–204.

of a few chaetae each. Other polychaetes have chaetae arranged in flattened fascicles usually arranged dorsoventrally. Each chaeta is produced from an invaginated epidermal cell (chaetoblast). The outer cell membrane of each chaetoblast is covered with microvilli, each of which produces a slender cylinder of chitin. These cylinders are glued together by scleroprotein produced by cells lining the invagination. All chaetae are formed the same way, through complex interactions between production of cylinders and glue secreted to keep the chaeta together and give the external shape. The chaeta may be tapering capillaries, but most chaetae are much more complex (**Figure 5**). A species may have a single kind of chaetae or two or more kinds; in some parapodia each chaeta may be different, but more usually groups of chaetae with similar structure are present. New chaetae are formed throughout the life of the worms, and distribution of different kinds of chaetae is carefully controlled and changes as the worm grows. In rows of identical chaetae new chaetae are produced at one end of the fascicle and drop out at the other end (e.g., hooks in terebellids). In syllids that often have few chaetae, and each chaeta differs from all other chaetae in a parapodium, replacement takes place in a one-to-one fashion. Special kinds of chaetae such as acicula, which are rods supporting long parapodia and various large spines often show signs of wear, an indication that they are not replaced or at least not replaced as often as other chaetae. The base of the chaetae (chaetal sac) is anchored with muscles running across the body cavity, making it possible to protrude and retract the whole fascicle or bundle since in most cases only a single set of muscles are present. Acicula and large spines often have their own investment of muscles and are independently movable.

The oligochaete taxa of the clitellates each have a limited number of kinds of chaetae, most have capillaries or spines. The echiurans have minimally a pair of large hooks, usually located ventrally behind the mouth. The sipunculans lack chaetae, but have epidermal hooks formed directly externally on the body.

The Nervous System

The nervous system consists of a dorsal brain connected by a double nerve ring running around the esophagus to double ventral nerve chords. The anterior part of the brain is located in the prostomium, but penetrates well into the peristomium or even into the next several segments in many species. In most groups the two parts of the ventral nerve chord are wholly or partially fused into a single entity; each segment always contains a pair of ganglia from which the segmental nervous system runs to the parapodial muscles, nephridia, gonads, and circulatory system. The gut is invested from a separate set of nerves from the lower part of the brain (stomatogastric nerves). Antennal nerves run from the anterior part of the brain, and a pair of nerves associated with the posterior part of the brain runs to the palps. Indeed, Orrhage has found a pattern in the emergence of nerves and internal connections in polychaete brains, showing that the limited number of nerves can be identified from one group to the next based on position and function.

The ventral nerve chord may contain two or more giant fibers associated with rapid retraction into burrows or tubes consisting of very thick nerves running from the anterior end innervating the longitudinal muscles directly with only a minimum of synapses. Other motor fibers are segment-to-segment loops passing along undulatory locomotory waves.

The clitellates have a nervous system resembling the one present in the polychaetes, In other annelids the main nervous system resembles the one present in the polychaetes, but segmented nature of other nerves is absent.

Sense Organs

Eyes are mostly eye-spots located on the prostomium or even directed on the upper surface of the brain. In some polychaetes the eyes become much larger when the species are sexually mature (e.g., nereidids), and the epidermis over the eye becomes a translucent lens. In a group of pelagic polychaetes (e.g., alciopin phyllodocids) the eyes are a very large camera construction with a distinct lens and with focal capabilities of considerable complexity. In the polychaete eyes, the sensory cells penetrate through a pigment layer (retina) into the space in which the lens is supported and the optical nerve is collected behind the pigment layer, thus the retina is reversed compared to vertebrate eyes.

The nuchal organs are usually located in pits, in short grooves or on short ridges near the junction between the prostomium and the first segment. The nuchal organs may be very large, complexly folded structures (caruncles) in the euphrosinids and amphinomids. And the epaulets present in some syllids are also nuchal organs. In some spionids the nuchal organs stretch along most of the anterior region of the worm as narrow, ciliated attached ridges. The presence of nuchal organs has been considered diagnostic for the polychaetes in relation to the clitellates, which lack these

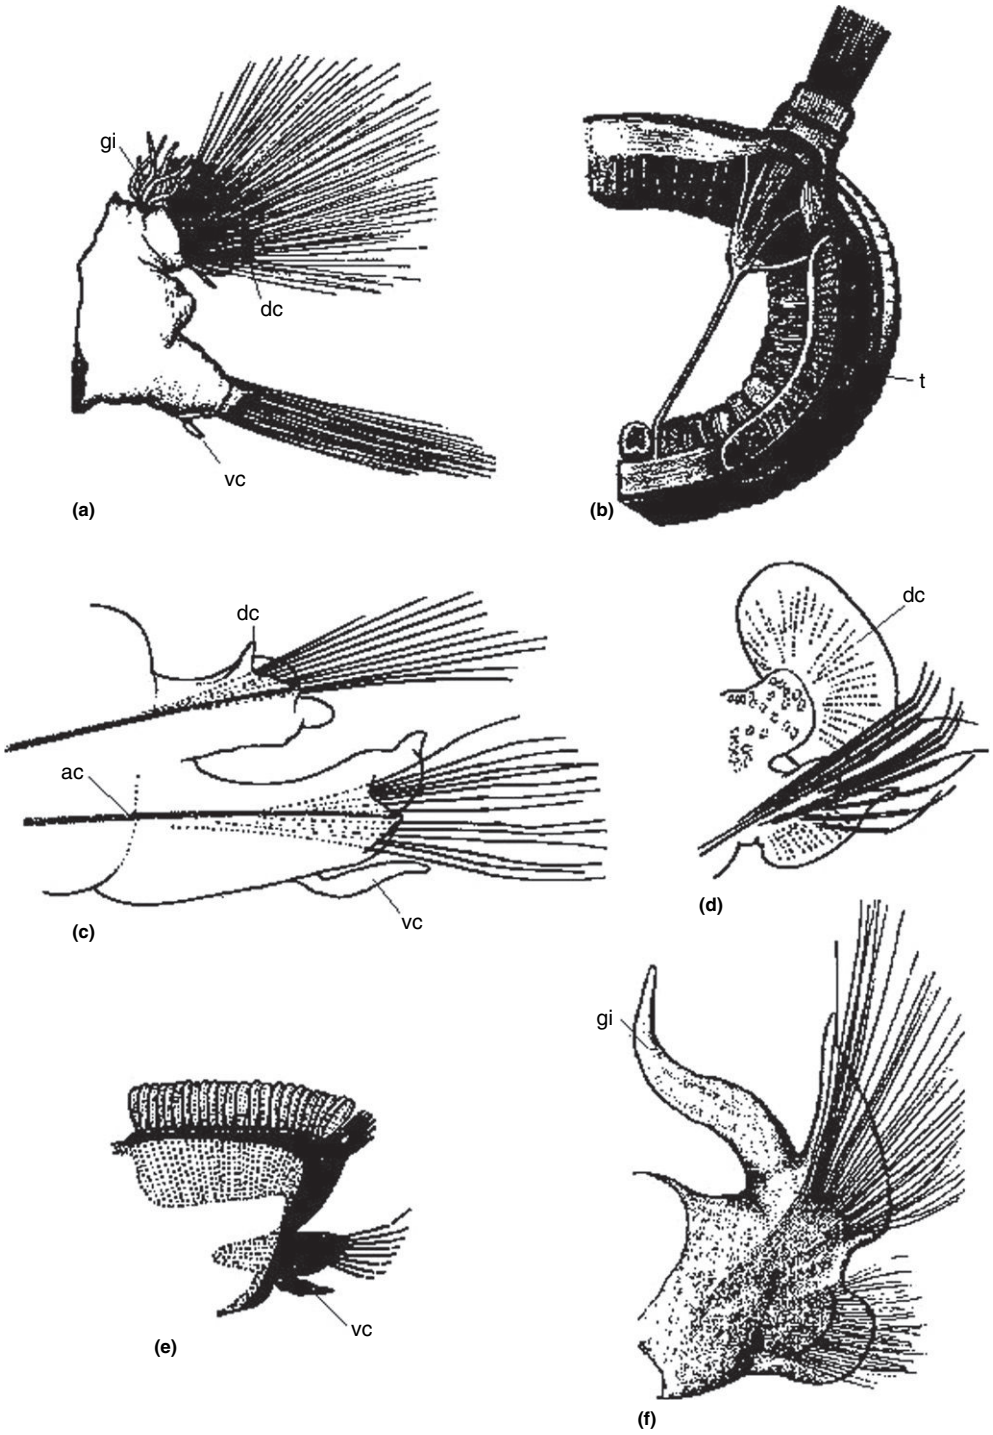

Figure 4 Polychaete parapodia. (a) Amphinomid; note similar rami. (b) Arenicold; note neuropodia modified to a torus and the musculature linking the base of the chaetae to the ventral body wall. (c) Paralacydoniid; note unequal rami and the notable presence of aciculae. (d) Phyllodocid; note large, foliose dorsal cirrus. (e) Chrysopetalid; note that some of the notopodial chaetae are large, flattened paleae covering the dorsum. (f) Spionid; note the dorsal flattened gill. structures. However, some polychaetes lack nuchal organs, and sensory structures closely similar to the nuchal organs are present in sipunculans, so the presence of these sensory organs may be a shared feature of the annelids and the loss among certain annelids may be a secondary phenomenon.

Ciliated lateral organs are located between the parapodial rami in many polychaetes, they are usually tufts of cilia in a shallow pit, but may form eversible papillae in some taxa. Similarly constructed patches of cilia have been reported from a variety of annelids and may form patterns of sensory organs

characteristic of each of the major groups. All these ciliated structures are assumed to be at least partially chemosensory, but the experimental evidence is usually missing.

Musculature

Musculature includes two pairs of longitudinal muscle bundles; these bundles are usually ovate in cross-section, but especially in species with massive longitudinal muscles, they are folded over, presumably to avoid buckling during strong contraction. The ventral pair is usually heavier than the dorsal pair, which in some worms (e.g., terebellids) form a thin layer between the upper edge of the notopodial and the dorsal midline. Circular muscles are usually considered to be present; however, at best they are present near the septal boundaries. Most of the other segmental muscles are associated with the parapodia, the chaetae, or are dorsoventral transverse muscles.

Whether these antagonists to the longitudinal muscles represent the remnants of a former complete layer of circular muscles has yet to be determined.

However, it appears likely since most other annelids have the longitudinal muscles represented by a relatively even layer and a distinct circulatory muscle layer is present. The clitellates have longitudinal bundles of muscles, and the small aquatic species lack circular muscles; however, the terrestrial earthworms have a well-developed layer of circular muscles.

Septa

Septa separating the segments are rarely complete, but in many cases they are sufficiently muscularized, with radiating and circular muscles to allow each septum to clamp down around the digestive tract and at least temporarily isolate each segment. In certain families one or more of the anterior septa may be complete (gular membranes) and may isolate an anterior part of the body cavity from the rest of the body.

Other than the polychaetes the septa in other annelids are reduced or missing except the separation isolating an anterior chamber of the body cavity from the rest of the body in the sipunculans.

Digestive Tract

The digestive tract is usually a more or less straight tube running from mouth to anus. The larval stomodaeal region (infolded ectodermal region in the mouth) may be elaborated into an eversible pharynx (proboscis). This pharynx may be axial or may include only the ventral side; it may be sac like or muscular. Jaws are present in some taxa; they are thickened regions of the cuticle and as such consist primarily of sclerotinized protein in which a variety of metal ions may be imbedded, or they may be calcified. Paired salivary glands are often present. The middle of the gut may be invested with a large blood sinus or is at least well supplied with segmental blood vessels. In postlarval siboglinids (Pogonophora and Vestimentifera) the gut is blind ending at both ends and the lumen of the gut is largely obliterated, but a very inflated specialized gut wall is present. The cells of this gut wall contain numerous commensal bacteriae. The scale worms have numerous segmentally arranged blind sacs attached to the midgut; at least some part of the intermediary metabolism takes place in these sacs, which also in part supplements the circulatory system in bringing nutrients to the tissues in which they are needed. Some polychaetes have a looped gut; in these taxa the septation is missing in the region that contains the loop. Looping allows for an increased length of gut in relation to the size of the worms.

The gut in other annelids is most frequently similar to the one in the polychaetes in that it runs from mouth to anus, except that it frequently is rather long and folded. The exception is Siouncula in which the gut is U-shaped, with the ascending and descending parts spiraled around each other. The anus is at the anterior end of the main body at the base of the retractable anterior part of the body.

Gills

Gills are present in a variety of taxa. They are usually associated with the notopodial but may be present anywhere along the body; they are recognizable as thin-walled extensions from the body wall containing a vascular loop in which the two limbs of the loop are linked through capillaries. This definition excludes the structures called gills in capitellids and glycerids, both of which lack a circulatory system; these structures cannot at this time be considered homologous with the gills present in taxa with closed circulatory systems. Functionally, any thin-walled extension from the body wall will have a gas-exchange function whether it structurally belongs to a given category of structure or not. This issue is of considerable phylogenetic interest in that gills must have evolved independently several times, while in other clades, morphologically different structures, including the notopodial cirri, have taken on respiratory functions.

Gills are absent in most nonpolychaete annelids; some leeches have extensions from the body wall with respiratory functions and the anterior feeding apparatus in the sipunculans have a similar function. The echiurans have paired anal sacs that they periodically flush, presumably bringing water into the sacs, which would bring oxygenated water into close proximity to the digestive tract.

Circulatory System

Circulatory systems may be complete, consisting of a dorsal, often contractile vessel, in which the blood flows anteriorly, one or two major ventral vessels, and capillaries connecting these vessels to the gut and to the rest of the organs. Some polychaetes lack the capillary beds and thus have an open circulatory system. And small species often lack a circulatory system entirely, presumably relying on diffusion for transportation of oxygen, carbon dioxide, and so forth. Shared absence of a circulatory system is not considered a feature of phylogenetic importance; it seems to be linked to a reduced body size.

Nephridia

Nephridia may be present already in the larvae as protonephridia; postlarval nephridia may be either protonephridia or metanephridia. Protonephridia open into the body cavity with intracellular slits; metanephridia open with a funnel. In all postlarval polychaetes, the inner end of the nephridia is located in the segment preceding the one in which the duct opens to the exterior. About 100 years ago Goodrich identified a series of possible fusions between the nephridia and the exit ducts for the gonads (e.g., protonephromixia, metanephromixia, mixonephridia). New information suggests that this classification may not represent the situation accurately, and that it is more complex than previously understood. Nephridia are often present in many segments, especially when the segments are similar in structure; however, in many polychaetes the number of pairs of nephridia may be limited to four or five. Excretory nephridia are always located anterior to nephridia, which functionally become gonoducts when the worms are sexually mature.

Gonads

Gonads may be present in many segments, or they may be limited to several or even just a few segments in the middle of the body. Sexes are most frequently separate, but hermaphroditic taxa are scattered throughout the group. The gonads are usually very simple, part of the peritoneal lining of each segment, sometimes attached to the transverse or oblique muscles. In many polychaetes only the first few cell cleavages leading to eggs and sperm take place in the gonads proper, the rest of the development takes place in the coelomic fluid in which the eggs and sperm float. The developing spermatocytes may have incomplete early mitotic cleavages, leading to flattened sheets or rounded balls of cells in which the head end of the sperm is embedded in the shared structure; these structures are called sperm morulae. The yolk of the developing eggs may be furnished by nurse cells, either in a layer or as two strings. However, in many species no nurse cells are present, but the coelomocytes function at least in part to furnish the building blocks of yolk for the eggs and the general nutrients to the developing sperm.

Reproductive Biology

Most species spawn in the water, the site of fertilization as well as development up to settlement; indeed, several species swarm on the surface, such as the palolo worms of tropical waters, sometimes while emitting luminescence (e.g., *Odontosyllis*). A few species have modified some of the parapodia for copulation, but this is rare and limited to certain small species. However, we are increasingly finding that females may store sperm in sperm receptacula, which may be segmentally arranged at or near the anterior end. Sperm morphology has been related to the modes of fertilization. The round-headed sperm with a short acrosome and a long tail has been considered primitive since it is present in taxa that spawn into the water column. When fertilization takes place elsewhere, the sperm usually has another structure, often with greatly elongated heads and short tails.

In taxa with both feeding and nonfeeding (or brooded) larvae, eggs are much larger in the taxa in which the larvae do not feed. Nonfeeding larvae are present in all major groups of polychaetes and in some families they are the only kind of larvae present. The shift between feeding and nonfeeding larvae must have evolved more than once; the direction in which this shift has taken place cannot be considered settled in many cases.

Early development may take place in open water, in deposited egg masses, in brood chambers of various sorts, or internally, in the body of the females. After the early cleavages, which follow a pattern called spiral cleavage, as in many related phyla, and gastrulation, a trochophora larva develops. The trochophore consists of any upper episphere with a sensory tuft of cilia on the top and often a pair of small eyes. The episphere is separated from the hyposphere by an encircling prototroch, a ciliary band that in the polychaetes may consist of anything from a single row of ciliated cells to a broad densely ciliated girdle. The mouth is located on the ventral side, immediately posterior to the prototroch and is often associated with a longitudinal midventral ciliary band, the gastrotroch. At the posterior end of the larva, a third ciliary band, the telotroch, is often also present. In feeding larvae the gut is fully developed and a pair of larval nephridia is present. When metamorphosis starts, segmentation starts posteriorly, just in front of the telotroch, internally the segments are first visible as paired mesoderm blocks on either side of the gut. These blocks eventually become hollow and the mesoderm forms the peritoneal lining and muscles and most other structures in the developing segment. The space inside each block becomes the secondary body cavity, the celom, which eventually contacts the exterior through nephridial ducts. Metamorphosis in most polychaetes is a gradual process of adding more segments with a progressive reduction in the prototroch and other larval structures; the body proportions of a newly settled juvenile may reflect what the adult worm will eventually look like, but in many cases considerable change in relative proportions of various body regions takes place during the later development. The body of the polychaetes may appear to consist of a series of repeated units, but as we become more familiar with postmetamorphic development it is becoming increasingly obvious that the polychaetes maintain integrated bodies with distinct proportionality between different regions.

The clitellates are hermaphroditic and, especially the terrestrial ones, have developed complex mechanisms to ensure fertilization and protection of the fertilized eggs. The clitellum, the excretory girdle will during the copulation secrete a cocoon in which the larvae develop. Clitellate development is always without a trochophore as described above for the polychaetes. Both the echiurans and the sipunculans have a trochophore. In the echiurans, metamorphosis follows a relatively brief trochophore stage. One unusual feature of the bonellid echiurans is that the larvae have indeterminate sex. If the metamorphosing larva settles directly on the substrate, it will become female; however, if the larva settles on the elongated prostomium of a female, it will become a dwarf male and live permanently connected to the female, essentially becoming a ready source of sperm when the female spawns.

The sipunculans follow the first trochophore with a prolonged larval stage in which they may stay in the plankton for several months. If an early trochophore happens to hit the substrate prematurely, it will not metamorphose, but will most likely die.

Systematics, Diversity, and Phylogeny

The phylum Annelida has recently undergone a massive restructuring as indicated above. The following outline of these changes follows some of the major changes, but all issues are yet to be resolved.

Traditionally the polychaetes were separated into errants and sedentaries (two equivalent groups in terms of numbers of species), since the 1950s this system has been replaced by one in which the group is separated into many orders, but without a clearly stated phylogenetic scheme to support the groups (see Fauchald 1977 for an example). The classification presented here was proposed by Rouse and Fauchald (1997)

(Figure 6); it will certainly be improved when more information becomes available. Especially important will be a clearly recognized linkage between the clitellates and the polychaetes. In particular, the group called Scolecida in Rouse and Fauchald turned out to be unsatisfactory when genetic information became available.

In addition to the approximately 80 families traditionally included among the polychaetes, a major change was

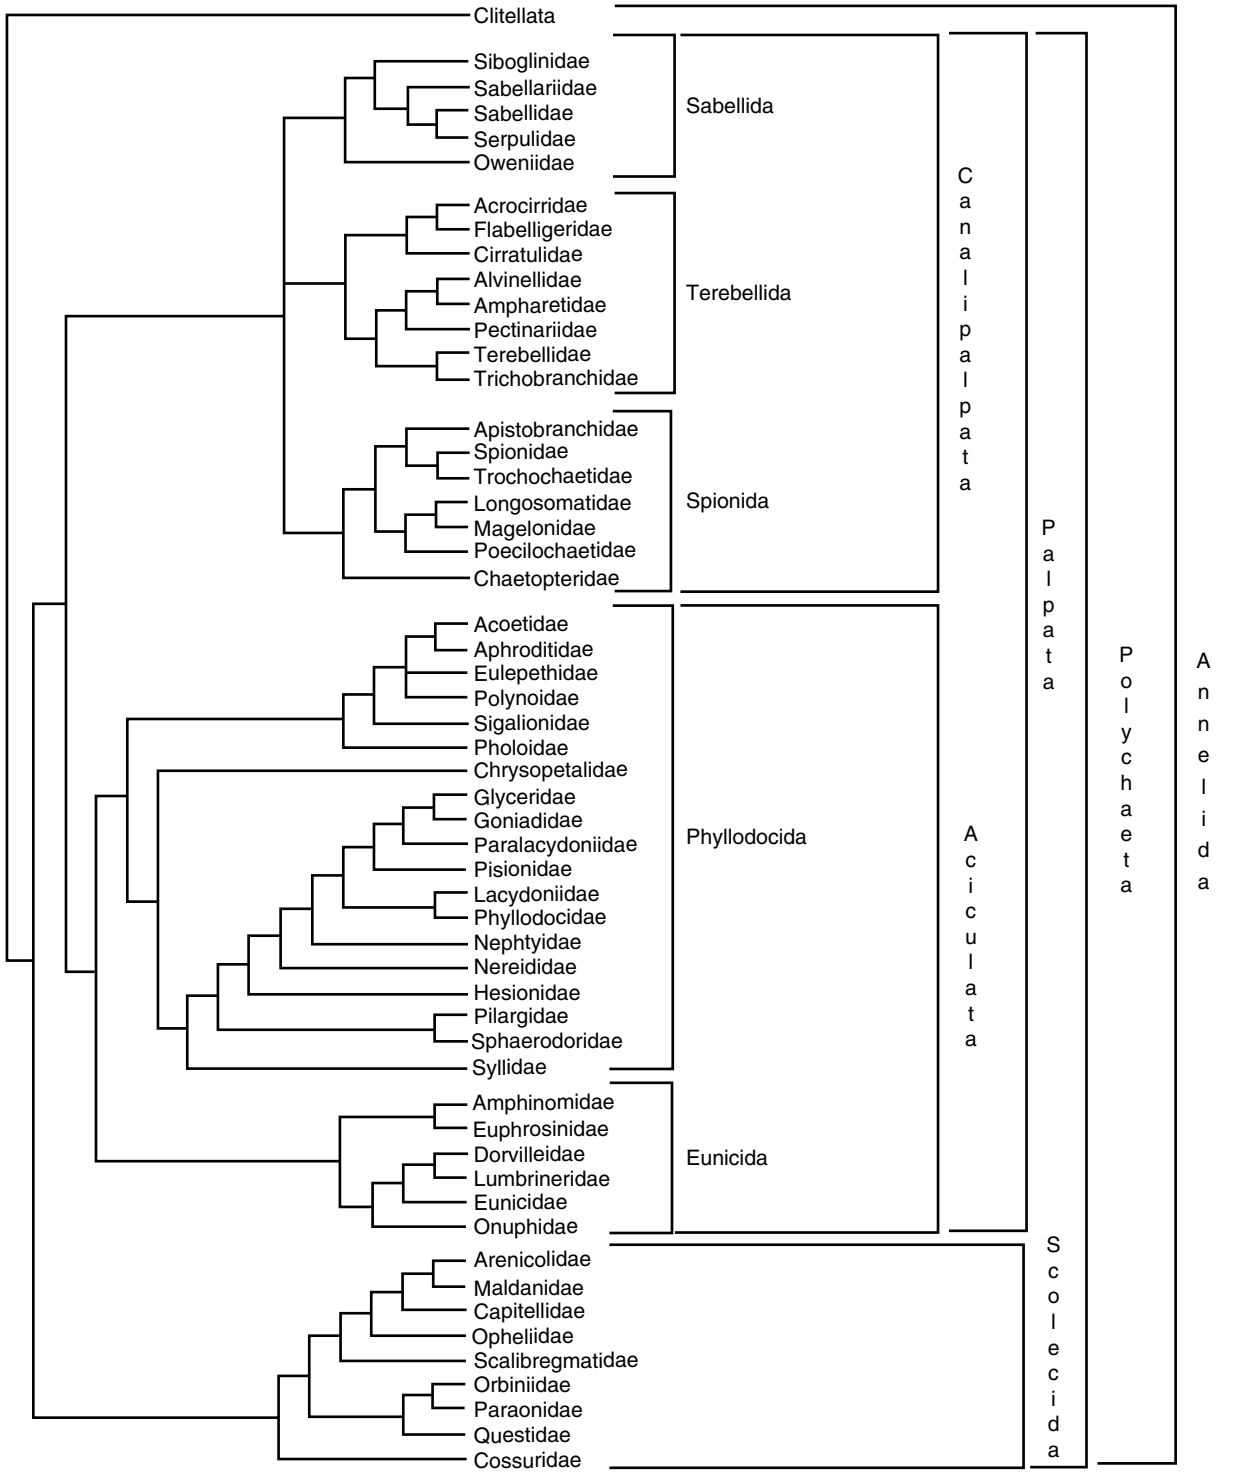

Figure 6 Diagram showing the current systematic subdivision of the Polychaeta. Only 54 of the 80 families have been included; most of the remaining families can be readily associated with the taxa where they fit but are sufficiently poorly known or lack so many features that including them would have distorted the current analysis. Eventually, we expect to be able to incorporate all families. Modified from Rouse GW and Fauchald K (1997) Cladistics and polychaetes. *Zoologica Scripta* 26(2): 139–204.

proposed by Rouse and Fauchald. The pogonophorans (including the vestimentiferans) have been considered a separate pylum (phyla). Their major features match the polychaetes well, and they are included here as single family polychaetes, Siboglinidae. Some of the unusual features, such as the "absence" of a gut are incorrect; the siboglinids have most tissues associated with the gut, but in the adults the gut is closed both anteriorly and posteriorly and the gut lumen is obliterated. Evidence from molecular systematics furnishes good criteria for including the siboglinids among the polychaetes, even if the exact placement among the canalipalpates is still uncertain.

Rouse and Fauchald included the myzostomids among the polychaetes; this group has been considered distinct for more than 100 years, and recently it has been shown that the apparent similarity to the polychaetes is incidental (see especially papers by Eeckhaut and collaborators). The myzostomids are associated with echinoderms and have a fossil record stretching back to the paleozoic, so they certainly have a long separate evolutionary history. Recent molecular studies link the myzostomes to the annelids again.

The fossil record of the polychaetes is, not surprisingly, uneven, considering that they are soft bodied with very few, readily fossilizable structures. They were present in the middle Cambrian (in the Burgess Shale) in taxa resembling in certain respects, both recent canalipalpates and aciculates. In the same material is also found *Wiwaxia*, which may or may not have been a polychaete, but which appears to share certain details with members of a recent aciculate polychaete family, Chrysopetalidae. Jaws of various polychaetes have been reported present from the Ordovician on, these jaws were originally considered a separate group, Scolecodonta, but are now considered disarticulated jaws of aciculate polychaetes, especially the euniceans, which are still common in all kinds of environments. Whole body fossils have also been reported from other Paleozoic strata, and the presence of recent families has been suggested. Many of the whole-body fossils lack the diagnostic characters of recent taxa so the presence is often difficult to document. Calcified tubes similar to those present among the serpulids are present from early paleozoic strata on, some of these tubes may have belonged to nonannelid taxa, but certainly some of them were serpulids. The upshot of the scattered records shows that most major taxa of polychaetes must have been present by the Ordovician and some clades may be even older than that. This suggests that each group has a long separate evolutionary history. Most of the groups were thus present before Pangaea was formed, which agrees with the very wide dispersal of all major polychaete taxa: they have been rafting on the continents. However, there is much evidence to show that individual species are capable of very rapid dispersal as invasive species, probably mostly through transportation of adults.

Polychaetes are important components of the bottom fauna at all depths of the oceans from beach sands to the soft mud of the deep-sea trenches. Recently a rich fauna of very unusual polychaetes has been found in both hot vents and cold seeps. Various polychaetes are also present in the pelagic environment throughout their life, more commonly the polychaetes have benthic adults but are present in the plankton for larvae for a varying period of time. In certain areas the polychaetes may make up as much as 90% of the standing crop of benthic macrofauna, so any account of life in and on the sea bottom must take into account the activities of these worms.

Polychaetes often appear to be very widely dispersed geographically, and some species are considered cosmopolitan. Careful studies have in many cases shown that the records on which these distribution maps were based are erroneous. More than one species have been called by the same name: later investigators have shown that what was originally thought to be a single taxon often represented several distinct taxa. This correction of geographical records is important for our understanding of the biodiversity of many areas, and is in part the result of increased quality of analysis based on the development of statistical techniques and the emergence of molecular systematics or has been demonstrated in experimental studies. Many polychaetes are genuinely widely dispersed however, possibly because they can be transported on ship bottoms and in ballast water. Other forms of accidental introductions also have been demonstrated. Importation of a species of abalone from South Africa to California for use in aquaculture brought along small sabellid polychaetes that burrow into the shell of the South African abalone; the sabellid escaped and is now doing damage to native abalones not only in aquaculture but also in the wild. Other polychaetes, especially members of the family Spionidae, have been transported with importation of oysters, they burrow into the shells of oysters, forming mud blisters, which may have serious consequences for the oyster industry in certain areas.

Polychaetes may move around at the surface of the substrate on which they live, but even the most active species are usually cryptic, nestling in cracks and crevices, under the cover of sea weed or debris or along the edge of rocks where these meet sand or mud. Many polychaetes from a variety of higher taxa form tubes or burrows in which they live more or less permanently. Some, such as the onuphid *Hyalinoecia*, are capable of moving their quill-like tubes along, but others, such as the related *Diopatra* are sessile; in this genus the tube consists of a gray matrix which, where it reaches above the substrate, is decorated with shell fragments, wood or sea grass debris, and sea weed. The sabellids, especially the larger species, form tough, but pliable tubes, but the closely related serpulids have their tubes impregnated with calcium carbonate. Some species, such as certain glycerids, live in complex galleries with several openings on the surface; the worms move around in the galleries so that they can intercept small prey organisms moving around on the surface of the mud or sand.

The presence of polychaete tubes creates a microenvironment in many areas so that the sheer presence of these worms modifies sedimentation patterns and influences the relationship between the surface of the sediment and the overlying water.

In general, polychaetes feed on anything organic. Some taxa are obligate carnivores, but most species will feed basically on any kind of plant and animal fragments present, alive or dead. Several species take food particles out of the water column, mostly by creating small back eddies in flowing water so that particles in transport in the water will drop out of the flow. Only the chaetopterids truly filter the water for contained food and are specialists of that mode of feeding.

The nereidid polychaetes have been shown to be capable of filtering as well, but they are not morphologically structured for this activity. This may be true for several other polychaetes that are capable of building temporary tubes and driving water through the tube with undulatory motions. Incomplete mucus plugs will fetch particles in the stream. Many polychaetes feed by capturing small, light-weight particles in mucus strands and transporting them to the mouth along the palps, feeding mainly on the light fraction of particles in bottom load transport at the water–sediment interface, often creating or taking advantage of irregularities in the bottom. Some polychaetes feed at depth at the bottom of their tubes (maldanids) and are thus capable of turning over sediments. The arenicolds are especially well known for their feeding in the intertidal sands and mud flats, these worms are large and as a consequence have considerable effect on the life conditions for all other inhabitants in the bottom. They are buried sufficiently deeply to avoid being the prey of plovers and other birds.

Certain polychaetes, such as the capitellids, include some of the most pollution-resistant species in the sea, capable of surviving in inner harbor waters where the organic pollution load is very heavy. Other polychaetes, such as some glycerids are extremely sensitive to change in sediment composition and oxygen levels in the water. This range of reactions to disturbance has made polychaetes much used in environmental research. Most of the taxa used have short generation spans and at most a very short larval life, making them ideal subjects for laboratory studies of heavy metal ions toxicity. Most of the species used in this kind of research can be maintained under very simple conditions and have contributed to giving polychaetes a reputation for being generally pollution resistant, but it is likely that this is a sampling error. The species used in research easily go into culture. The more sensitive taxa are much more difficult to keep in culture, but may be more generally characteristic of the group as a whole in terms of physiological requirements.

The clitellates include three ecologically very different groups: the small, fresh-water and marine microdriles; the large, terrestrial earthworms, and the leeches. The microdriles are at least partially very widely dispersed geographically, but thanks to increased study, characteristic faunal elements are becoming better documented. The earthworms include several species that have been transported by humans in soil. Many of them are invasive and move into new environment easily.

The leeches are interesting in that they are essentially carnivores, or parasitic on animals, but phylogenetical they are derived from groups that appear to have been feeding basically on detrital particles. The leeches are present in all three major environments, marine, freshwater, and terrestrial. The terrestrial leeches are linked to high-humidity environments. The best known leeches include the bloodsucking leeches, *Hirudo medicinalis*, which were used in bloodletting for curative purposes in Western medicine. Some leeches are still used in surgery in helping with removing blood clots and other material at or near an incision. The leeches that have been sold as medicinal leeches turn out to belong to more than one taxon; but apparently the curative role is independent of species.

Echiurans are present in soft sandy and muddy marine environments where they can build up very dense populations. The best known echiuran is perhaps *Urechis caupo* (the fat innkeeper) from the US west coast. This is a very large, sac-like echiuran living in burrows in which it hosts a whole fauna of associated animals, most of whom live by stealing the food-nets produced by their host.

The sipunculans are present in most marine environments, they usually live in burrows from which they can evert their anterior end with the feeding tentacles and essentially brush up food particles from the surrounding of their burrows. They are often found in empty snail shells, in cracks and crevices in rocks and corals and even in the mangrove root mats in tropical environments. Because of their extended larval life, many species have been reported to be widely dispersed, but exact documentation of the relationships among the populations is often missing.

Glossary

Anhydrobiosis State of dormancy in various invertebrates due to low humidity or desiccation.
Cuticle Noncellular external layer of the body wall of various invertebrates.
Gubernaculum Sclerotized trough-shaped structure of the dorsal wall of the spicular pouch, near the distal portion of the spicules; functions for reinforcement of the dorsal wall.
Hypodermis Cellular, subcuticular layer that secretes the cuticle of annelids, nematodes, arthropods (see epidermis), and various other invertebrates.
Pseudocoelom Body cavity not lined with a mesodermal epithelium.
Spicule Bladelike, sclerotized male copulatory organs, usually paired, located immediately dorsal to the cloaca.
Stichosome Longitudinal series of cells (stichocytes) that form the posterior esophageal glands in *Trichuris*.
Stoma Mouth or buccal cavity, from the oral opening and usually includes the anterior end of the esophagus (pharynx).
Synlophe In numerous Trichostrongylidae, an enlarged longitudinal or oblique cuticular ridge on the body surface that serves to hold the nematodes in place on the gut wall.
Vermiform Worm shaped with tapering form both posteriorly and anteriorly.

What is a Nematode? Diversity in Morphology

General Characteristics and Synapomorphies

Despite numerous assertions that appear in the literature stating that nematodes are morphologically conservative, the contrary is actually true: Species of the phylum Nemata are extremely variable in their morphological characteristics. Because of this diversity, almost any broad statement regarding their anatomy probably should be tempered or qualified. Nevertheless, in general, nematodes are nonsegmented worms that generally lack external appendages. Most are vermiform, with tapering anterior (**Figure 1(a)**) and posterior ends (**Figure 1(b)**), cylindrical in cross section, and covered with a usually translucent (**Figure 1(c)**), flexible acellular cuticle secreted by an underlying cellular hypodermis. The cuticle may be smooth (**Figure 2**) or ornamented with rings (**Figure 3(a–c)**), longitudinal striations, spines (**Figure 3(b)**), or spikes or it may have well-developed wing-like structures called lateral alae very commonly on the externo-lateral surfaces (**Figure 4**). Some marine species have long setae (genus *Draconema* Figures 5(a), (b), and 6), which are modified sensory papillae that are probably used in movement and in detecting their environment. In contrast to all other nematodes some marine species have eye-spots that enable them to detect light in their environment (e.g., genus *Thoracostoma* **Figure 7**).

The fine-structure of the external body-cuticle is complex, acting to protect the animal from the external environment allowing it to remain homeostatic inside. The cuticle can be extremely resistant, and depending on the nematode species and its life-history attributes, for example, the cuticle of the nematode may be able to resist digestion in the most inhospitable stomachs in the vertebrate world. Whereas, nematodes may be extremely delicate, able to exist intact only within the osmotically balanced tissues of other animals (e.g., members of the Order (O) Filaroidea) and if moved from the isosmotic solution to one with fewer salts, they may explode and die in a most amazing display.

Nematodes are called "pseudocelomates" because in most forms, their celom is not completely lined with mesodermally derived cells and they are triploblastic. Possessing no circular body muscles, movement is accomplished by contraction and relaxation of longitudinal muscles in apposition to a hydrostatic skeleton. The body wall, is flexible and very strong. All nematodes maintain their form because their body fluids (in the hydrocoel) are under a positive pressure, relative to their environment, analagous to the way a water balloon maintains its shape. The cross-section in **Figure 8** shows *Vexillata* (a nematode that occurs in rodents of the superfamily Geomyoidea, and recently discovered in other rodents) the round shape of the body under the cuticle supports spines or aretes (the whole structure being called the synlophe). Nematodes have a complete digestive system with an anterior stoma just behind the mouth and usually a tri-radiate or triple muscle-pumping type of esophagus (**Figure 1(a)** and **(c)**) that can be muscular or glandular in structure (or both as occurs in certain species of the Filaroidea). The intestine, tubular in form, (**Figure 1(c)**) is usually a single cell in thickness and is lined on the peritoneal side with a thin collagenlike material and, internally, the cells are lined with microvilli to increase the absorptive surface area of the tubular intestine (Grassé, 1965; Maggenti, 1981; 1991a). The tubular intestine extends from the posterior of the esophagus straight to the anus or cloaca, sometimes showing outpouched cecae (blind sacs) or diverticulae near the esophageal–intestinal junction **Figure 9**.

Most nematodes are sexually dimorphic with separate sexes (diecious or amphigonus) and oviparous; however, some are ovoviparous and some are viviparous. Males usually have a cuticularized spicule or pair of spicules that are used to assist in the transfer of sperm to the females. Many species also have a gubernaculum (seen extended from the cloaca of a species of *Ansiruptodera* in **Figure 23**) that guides the spicule during copulation and also eversion of the spicules. Some species are hermaphrodytic and in these cases the nematode produces both sperm and ova from the ovotestis of the same

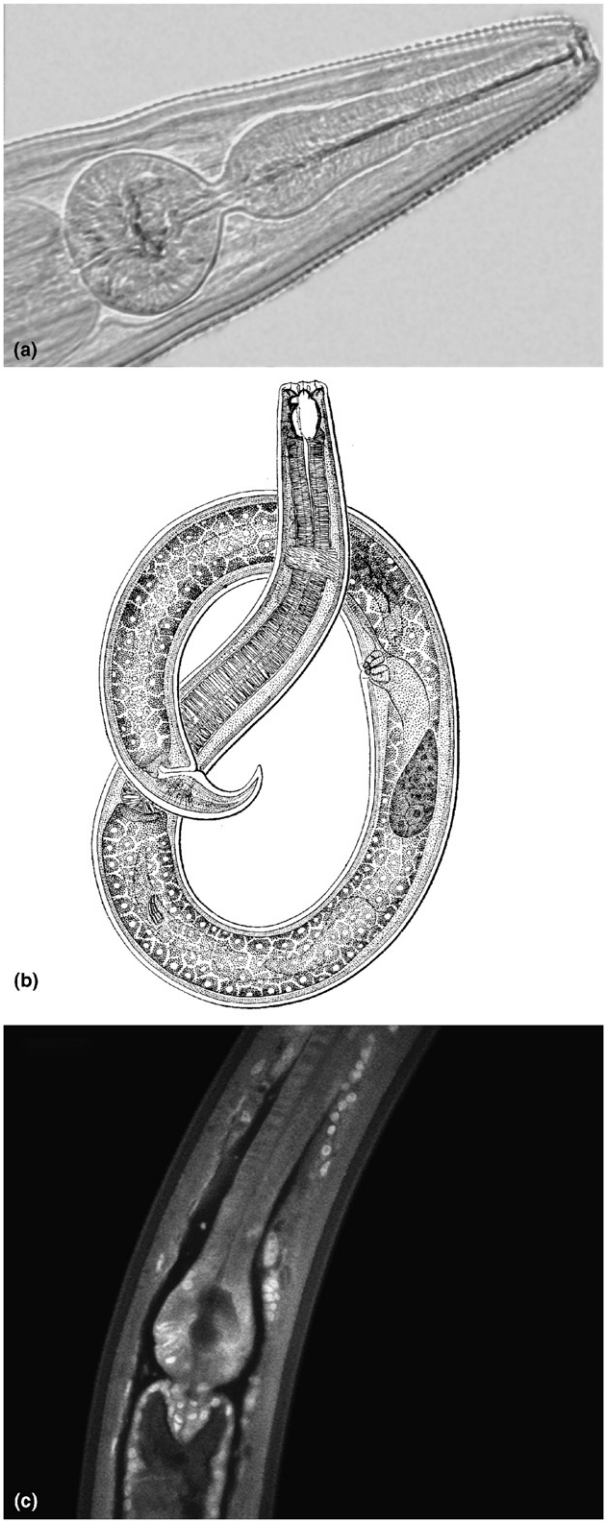

Figure 1 (a) Anterior end of *Didelphoxyuris*, the pinworm of South American Marsupials, showing the small anterior stoma at the narrow end, followed by the well-developed muscular esophagus with a large posterior bulb. The esophagus is tripartite and serves as a muscular pumping organ, pumping food into the intestine. (b) Whole drawing of a predatory nematode of the genus *Mononchus* showing the general structures of a nematode including the tapering anterior and posterior ends and the ventral vulval opening just posterior to midbody. The stoma is heavily cuticularized and bears a spike or spine that is used to puncture the cuticle of the prey. (c) Confocal microscopic image of the exophageal bulb and posterior part of the esophagus of a species of *Pratylenchus*. The cuticle can be seen as the outer light outline of the nematode with an underlying brighter layer showing the cellular hypodermis. The bulb shaped posterior part of the esophagus attaches via a valve to the single cell thick-tubular-intestine, shown here as an optical section just posterior to the esophageal bulb.

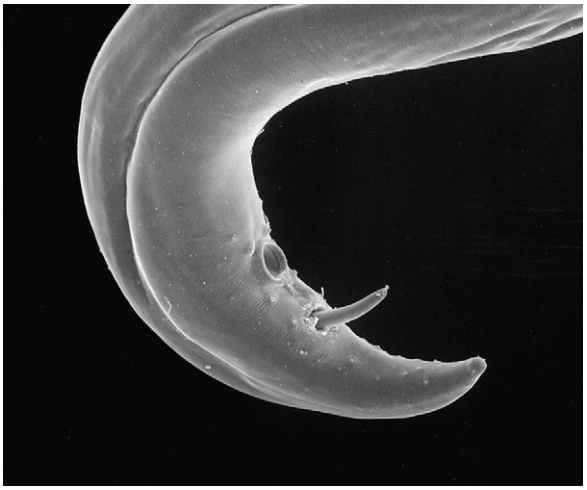

Figure 2 Posterior end (tail) of a male *Paraspidodera* showing the relatively smooth cuticle, a sucker just anterior to the opening of the cloaca, and one spicule protruding from the cloaca.

individual at different times during ontongeny (Maggenti, 1991a; Malakhov, 1994).

A synapomorphy of the Nemata is the presence of non-contractile axonlike myoneural processes or extensions that run from the contractile or body portion of muscle cells to the neural junctions of the nerve cords.

Their width is usually less than 2 mm, even when extremely long. However even here there are exceptions, with the giant kidney worm, *Dioctophyma renale* occurring in mustelids and canids sometimes attaining a size of greater than 15 mm by 1000 mm. The eggs of nematodes are also very similar in size with most ranging from 50–100 µm long by 20–50 µm wide with the exception being those of the antarctic marine nematode *Deontostoma timmerchioi* (40 mm in length of body) that has eggs that range from 870–1100 µm long by 240–350 µm wide (huge by nematode standards).

As mentioned above, nematodes are extremely diverse in size, shape, and structure. The following will only briefly touch on the expansive subject of nematode morphological diversity; for additional reading and exploration see the essential works and references therein of Maggenti (1981); and Grassé (1965 a and b).

External Covering – The Cuticle

An example of diversity in shape is that of the complex cuticular aretes found in species of the O. Strongylida: Trichostrongyloidea (parasitic in vertebrates) in which the exocuticle is modified into a series of cuticular aretes called the synlophe

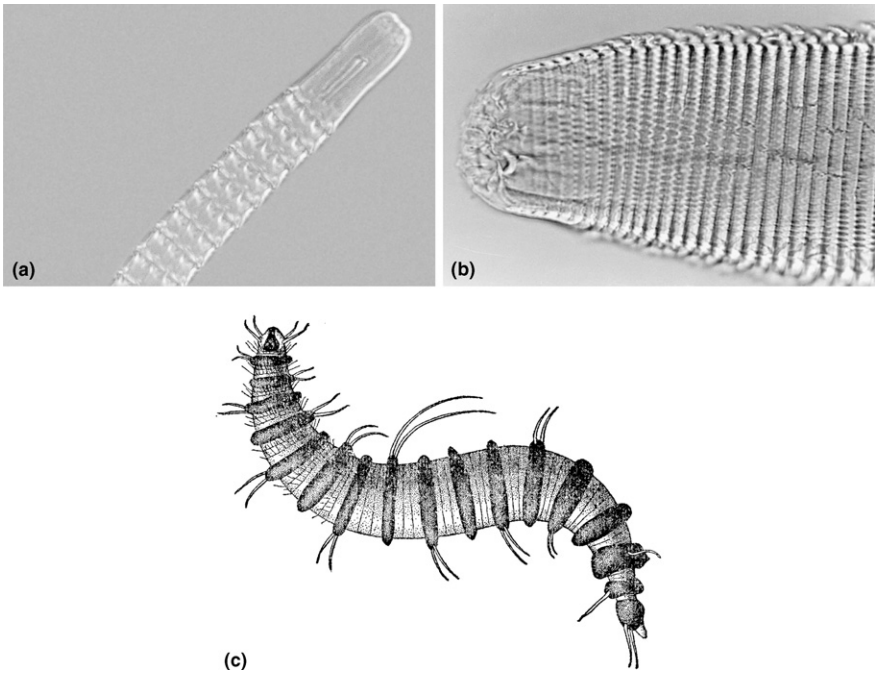

Figure 3 (a, b, c) Anterior ends of marine nematodes showing rings and spines on the cuticle. (c) Whole drawing of a marine nematode of the genus *Desmoscolex* showing heavily cuticularized rings and long setae.

Figure 12. In these forms, it is thought that the ridges running down the length of the body of the nematode are used in maintaining their position in the intestine of their hosts (Figure 8). Other forms have an exocuticle composed of serrated ridges (Figures 3(a), (b), 10, and 11), bumps, or may be very smooth (Figure 2). Some groups (Heterakoidea – parasitic commonly in birds and mammals) possess large cuticularized suckers just anteriad to the cloaca that are surrounded by sensory papillae that evidently allow the male to find the female in the intestinal tract of the host as in *Paraspidodera* of rodents (Figures 2 and 13) and *Ansiruptodera* from rodents (Figure 23). Marine nematodes of the genus *Draconema* (Figures 5(a) and 6) and *Desmoscolex* (3c) have a wildly modified cuticle relative to most nematodes and very large hair-like and segmented cuticular setae that the nematodes use for both movement and detecting its environment (Figures 5(a) and 6). One curious structure that occurs in all Nemata is the amphid, a highly variable sensory organ that can be very obvious as in *Desmodera* (Figure 10) or very inconspicuous as in *Chambersiella* (Figure 18).

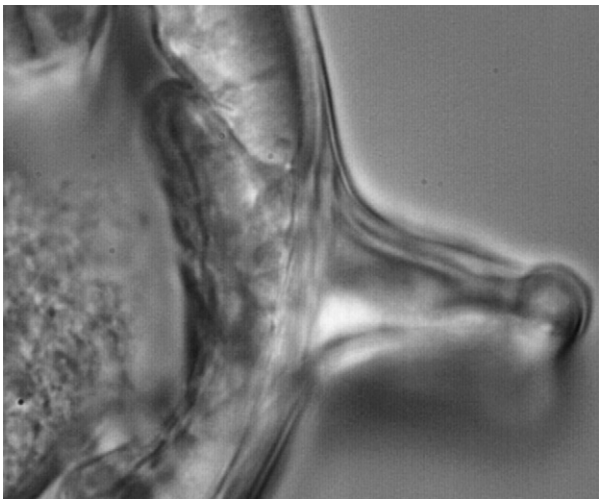

Figure 4 Lateral alae of *Aspidodera*, a parasite of South American xenarthrans, marsupials, and rodents. The ala or wing runs the length of the body possibly providing support for the nematode in the gut of its host. The cellular hypodermis of the nematode can be seen just inside the translucent cuticular layer.

The Alimentary Canal

The mouth of the nematode (Figure 14(a)) provides the anterior opening to the external environment, which connects to the stoma leading posteriad to the muscular esophagus (Figures 15–18). The stoma may be quite reduced or absent as in the case of members of the Trichostrongyloidea (O. Strongylida) or they may be well developed such as that found in *Clarkus* (Figure 16) and *Mononchus* (Figure 1(b)) and capable of inflicting damage on prey items or it may be modified into horny toothlike structures that are used to attach to the intestinal villi of the host animal (e.g., *Ancylostoma* Figure 19). In mammalian gut parasites of the genus *Trichuris* (Adenophorea: Trichuridae) the stoma is lacking and the esophagus is formed of stichocytes comprising a stichosome, which is glandular in function, but many other plant-parasites such as the Adenophorean ectoparasitic, below ground root-feeders (capable of transmitting viruses between and among plants *Xiphinema*, *Longidorus*, or *Dorylaimus:* O. Dorylamida: Longidoridae) have a tubular stoma with the posterior parts of the stoma modified into a spear that is used to penetrate plant

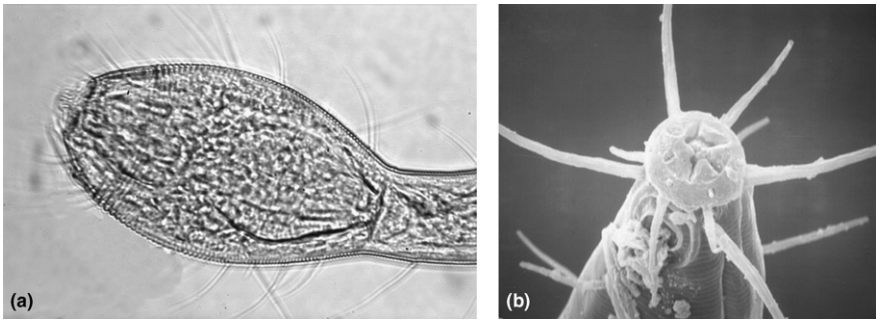

Figure 5 (a, b) The expanded head with visible cuticularized stoma of a species of *Draconema*, a marine nematode. Long setae that are probably used to move and to sense the environment are visible in this photograph. (b) Scanning electron micrograph of the anterior end of a marine nematode showing the long setae and a well-developed amphid just ventral and posterior to the lip rings.

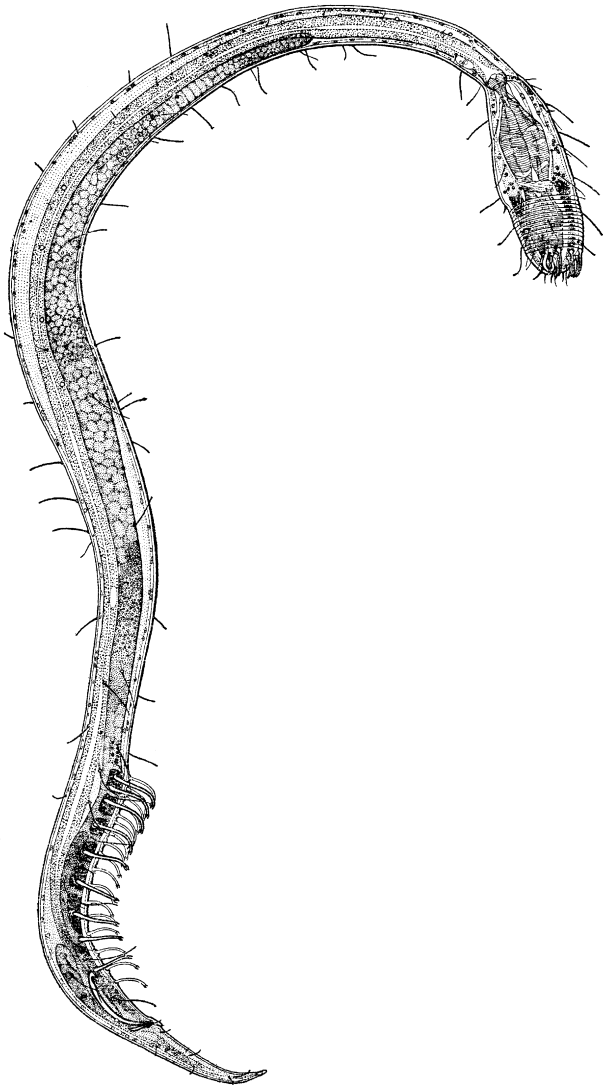

Figure 6 A whole drawing of a male of *Draconema* sp. illustrating the large setae, spicules, testis, and large expanded stoma and head.

Figure 7 Cuticularized "eye-spots" in the marine nematode *Thoracostoma.* Located at about the mid-part of the esophagus, this nematode can detect light in its environment.

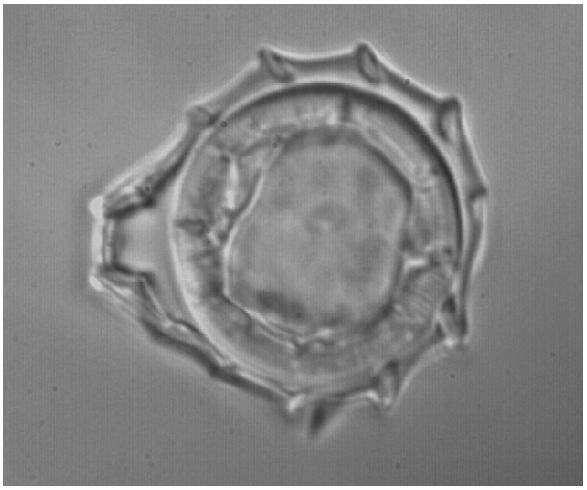

Figure 8 Cross section at midbody of *Vexillata armandae*, a species of nematode parasitic in rodents of the genus *Perognathus* in New Mexico, USA. This photograph shows the spines (aretes) in the cuticle, called the synlophe in Trichostrongyloidea. Inside is the hypodermis lining the body of the nematode. The reproductive tract and the intestine are not visible in this photograph.

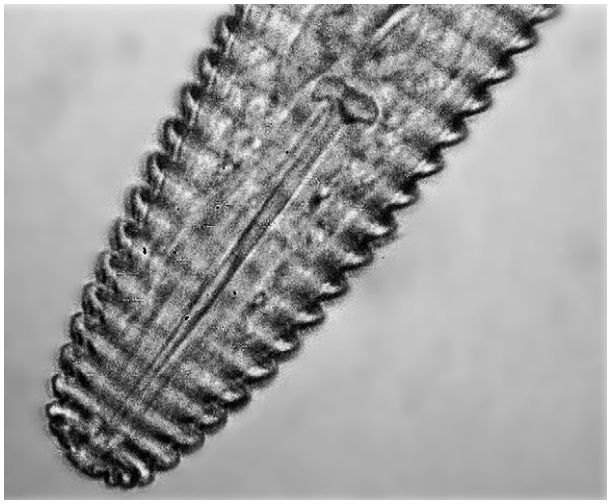

Figure 9 Anterior end of a species of *Criconemoides*, an external root feeding plant parasite. The rings of the cuticle can be seen from the head end posteriad, and the strong cuticularized stomatal spear is clearly visible in this photograph.

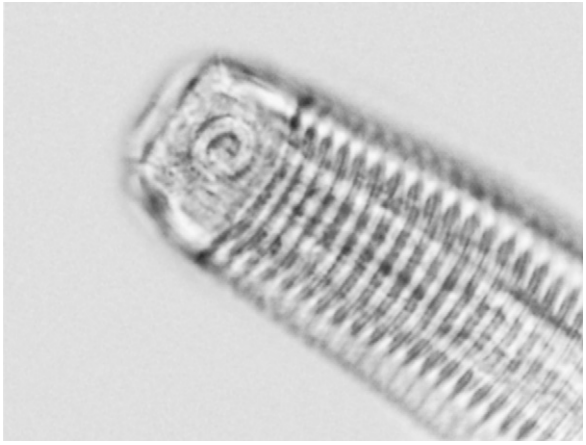

Figure 10 Anterior end of a marine nematode of the genus *Desmodera* showing the rings of the cuticle and a well-developed circular amphid.

cell-walls as in *Dorylaimus stagnalis* (**Figure 20**). The Secernentean plant endoparasitic nematode of the genus *Pratylenchus* (**Figure 21(a)**) also has a modified stomatal spear (much more delicate than those found in *Dorylaimus* sp.) with which it penetrates plant cells as the nematode moves through the tissues and cells of the plant (usually below ground).

The Reproductive System

The reproductive system of most animal parasitic nematodes is adapted to produce extremely large numbers of eggs (e.g., *Ascaris*). Some characteristics of larger animal parasitic nematodes include very large body, two large ovaries, and an equally large uterus. Free-living nematodes generally have much smaller bodies, and are therefore individually less prolific. However, the reproductive systems of most nematodes have the following basic structural similarities: Most

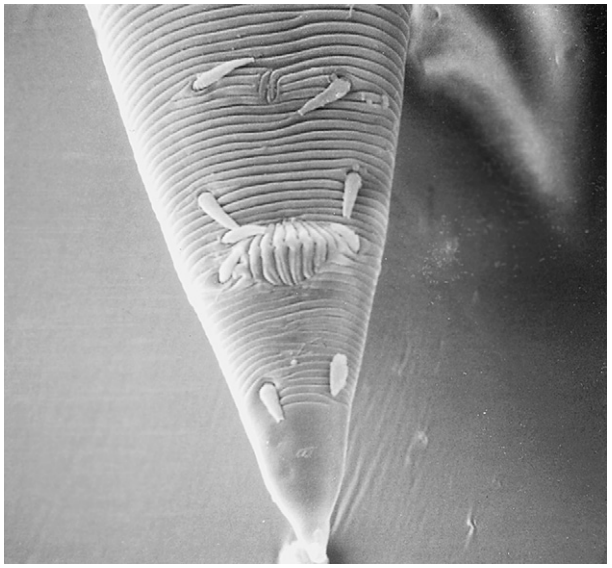

Figure 11 Scanning electron micrograph of the posterior end of a male marine nematode showing rings of the cuticle and small papillae lateral to the cloaca.

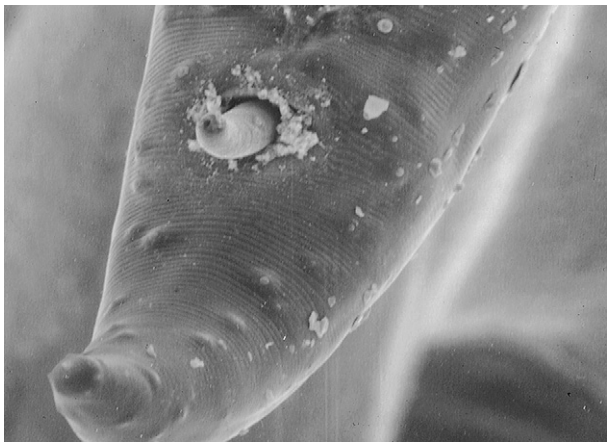

Figure 12 Scanning electron micrograph showing the posterior end of a species of *Paraspidodera* (a parasite of the cecum of rodents of the genus *Ctenomys* in Bolivia) with a spicule everted.

females have two ovaries, one anterior (as in *Pratylenchus* **Figure 21(b)**) and one posterior, each connected to an oviduct and uterus with the uteri connecting to the vagina, terminating in the vulva. Males usually have one testes as in the Secernentea or two as in the Adenophorea, a seminal vesicle and a vas deferens (Maggenti, 1991a) connecting to the outside via the cloaca (**Figure 13**), which is a joining of the reproductive system and the rectum. Secondary sexual organs in male nematodes are usually much more pronounced and variable than that of the female (**Figures 2**, **6**, **11**, **12**, **13**, **22**, **23**, **24**, and **25**) and most males have one or two spicules (**Figure 22**), a spicular pouch, sometimes with a spicular sheath (**Figure 24**), and a gubernaculum. (**Figure 23**). Some males of the O. Strongylida have a well-developed copulatory bursa (**Figure 22**).

Figure 13 Close up scanning electron micrograph of the sucker and cloacal opening of a species of *Paraspidodera* (a parasite of the cecum of rodents of the genus *Ctenomys* in Bolivia). Numerous sensory papillae can be seen on the cuticle around the cloaca.

Some plant-parasitic nemas produce eggs directly into the plant where the nematode lives (in the case of species of the genus *Pratylenchus,* the female produces eggs that hatch within the tissues of the plant and the juveniles begin feeding), whereas in others such as *Heterodera* (which are ectoparasites) the body of the female fills with eggs, forming a sac that eventually dries and transforms into a resistant cyst with the juveniles within capable of resisting environmental extremes.

The Ubiquitous Nature of Nematodes

There are few habitats on earth unoccupied by nematodes. Over a century of both biological surveys and informal collecting has led many biologists to believe that the Phylum Nemata is probably the most ubiquitous of all animal groups. Early in the history of scientifically based biological investigations, pioneers of microscopy opened a new window into the previously unseen microscopic world of the soils.

Descriptions of the "invisible" life seen by pioneers of microscopy such as Antony van Leeuwenhoek evoked images of a wonderfully diverse and dynamic community of worms and other organisms. Subsequent investigations by other early researchers began to open up the unseen world of the nematodes.

Early Views of Nematode Diversity – The Human Perspective

Humans have been parasitized by nematodes from the earliest times. Eggs of the pinworm *Enterobius vermicularis* and the whipworm *Trichuris trichuria* occur in coprolites dated to about 7000 years old (y.o.) from dry areas of Peru and eggs of the hookworm *Ancylostoma duodenale* have been reported from coprolites dated to around 7230 y.o. in eastern Brazil (Arujo *et al.*, 2008). *Ascaris lumbricoides* has been positively identified from human coprolites dated to about 28,000 y.o. from caves in France, but this is the only occurrence of a record this old. The seeming dearth of other nematodes from human remains older than about 7000 years appears to be due to the fact that organic material comprising the coprolites themselves do not preserve well enough to last that long (Karl J. Reinhard, personal communication).

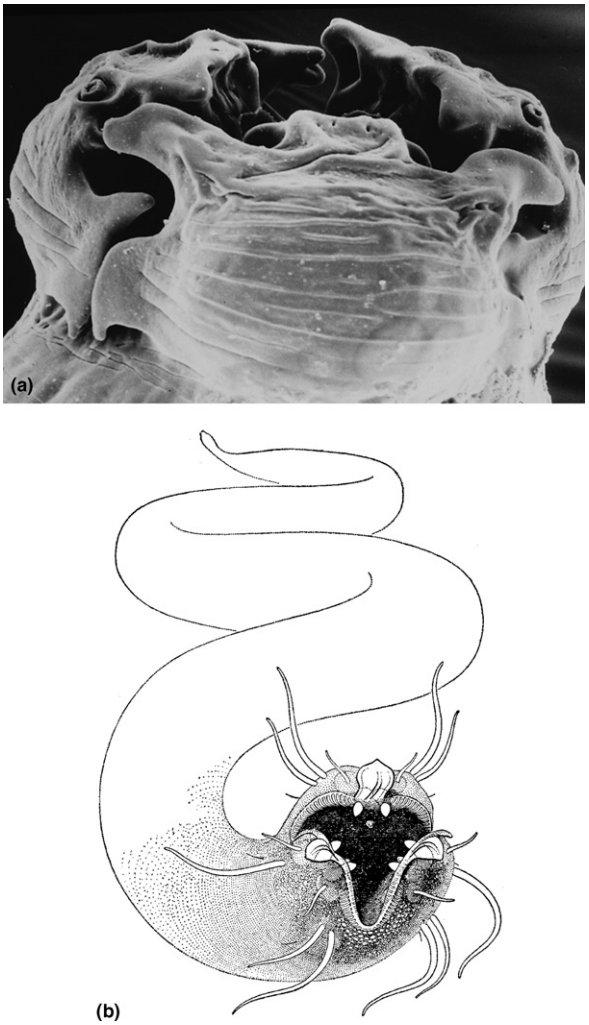

Figure 14 (a) Anterior end of a species of *Paraspidodera* (a parasite of the cecum of rodents of the genus *Ctenomys* in Bolivia) showing three huge lips, the stomatal opening in the middle of the lips and large anteriorly directed sensory papillae on lips 2 and 3 near the outer part of the photograph. (b) Head-on-view of a predaceous nematode as might be seen from the perspective of a mild mannered bacterial feeding form such as *Caenorhabditis* just before it is devoured.

In what is thought to be the oldest surviving written account of *Ascaris* in humans (dated to approximately 4700 y.o. (in China)), foods to avoid and a description of the symptoms of humans infected with these worms were accurately given (Maggenti, 1981). In the area of the Nile River Valley, early Egyptian physicians recorded the presence of both *Ascaris* and *Dracunculus* (the "Guinea Worm") in an ancient papyrus manuscript (written by Egyptian physicians around 3552–3550 y.o.) which was obtained and translated by the Egyptologist "Ebers" in 1872 (Chitwood and Chitwood 1977; Maggenti, 1981). In the extant literature, the first mention of a nematode from a nonhuman animal was by Hippocrates

Figure 15 Anterior end of a species of *Ansiruptodera* from a rodent from Bolivia showing the anterior end of the muscular esophagus attaching to the partially muscular and cuticularized stoma.

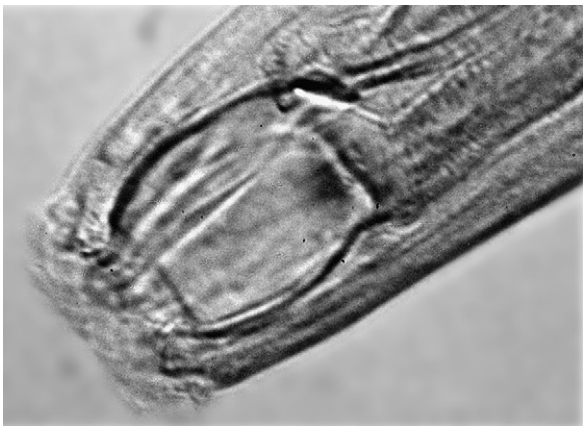

Figure 16 Heavily cuticularized stoma of a predaceous nematode of the genus *Clarkus*. This species is a soil predator living in rhizosoil of grapes in Northern California.

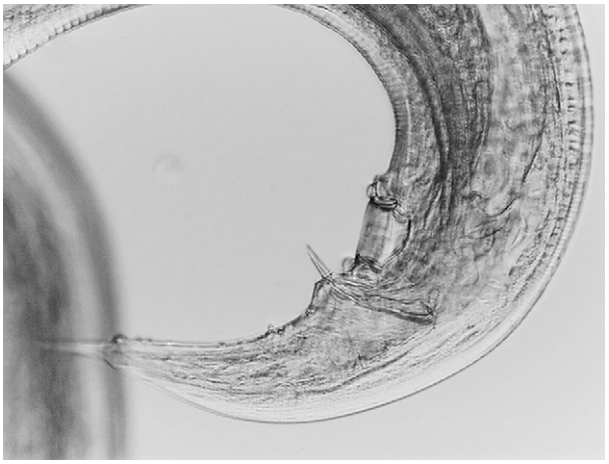

Figure 23 Posterior end of *Ansiruptodera* from a rodent of the genus *Oxymycterus* from Bolivia. The gubernaculum can be seen protruding from the cloaca of this specimen. The cuticularized sucker is also easily visible surrounded by sensory papillae.

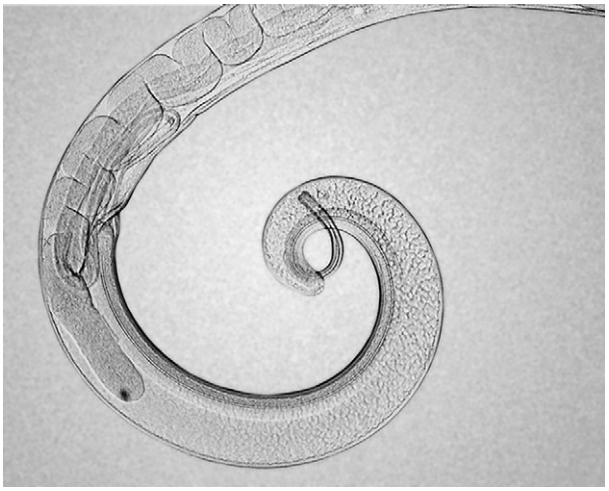

Figure 24 Posterior end of *Trichuris* from a Bolivian species of *Ctenomys*. The long spicule and everted spicular sheath can be seen.

about 2430 years ago where he described the occurrences of pinworm nematodes of both horses and human females. From that time, little further was discovered until Albertus Magnus and Demetrios Pepagomenos (in the thirteenth century, Rausch, 1983) recorded nematodes from falcons (also see Chitwood and Chitwood, 1977).

With the development of the microscope and the emergence of Europe from the dark-ages, knowledge of nematodes as parasites of plants and animals and of free-living forms expanded rapidly. It was found that nematodes occurred everywhere people looked, in fact, Anton van Leeuwenhoek first recording the presence of vinegar eels "*Anguillula aceti*" in his vinegar stored for personal use in a letter dated 21 April 1676 although he was not aware that others had reported finding nematodes some time earlier (Dobel, 1932).

Recent estimates of infections of humans with common human parasitic nematodes give the following numbers

(Crompton, 1999): Of a total human population size of about 6 billion individuals (in the year 2000) the strongylid hookworms, Ancylostoma duodenale and Necator americanus infect about 1,298,000,000 (22%) and the large intestinal nematode, Ascaris lumbricoides occurs in about 1,472,000,000 (25%) people at any one time in the world. Obviously, many people harbor more than one species of nematode at a time, and it is common for people to sport Ascaris, Necator, Trichuris, and Enterobius simultaneously. The author provides the following estimate to indicate just how important these organisms are in the web of life on earth. To put the number of infections of just humans in perspective, the author made the following extrapolations: An adult female Ascaris produces 200,000 eggs per day at an average rate of about 5grams of eggs per year. Actual data for Ascaris in humans that are infected show an average of 18 worms per infected person. Given that ½ of these are females, the author calculated that nine worms per person will produce about 45 grams of eggs in the feces of the host per year. In one year the total population of Ascaris in humans worldwide is conservatively estimated to produce 66,240,000 kg or 66,240 metric tons (72,864 tons (English)) of eggs; this is equal in weight to about 348 large adult blue whales, 8,832 adult male elephants, or 364 fully loaded railroad coal cars.

Estimates of the number of human infections in the year 2000 by other species of parasitic nematodes are shown in **Table 1**. At the present time, approximately 138 species of nematodes have been reported from humans (Crompton, 1999) with 32–36 being host specific.

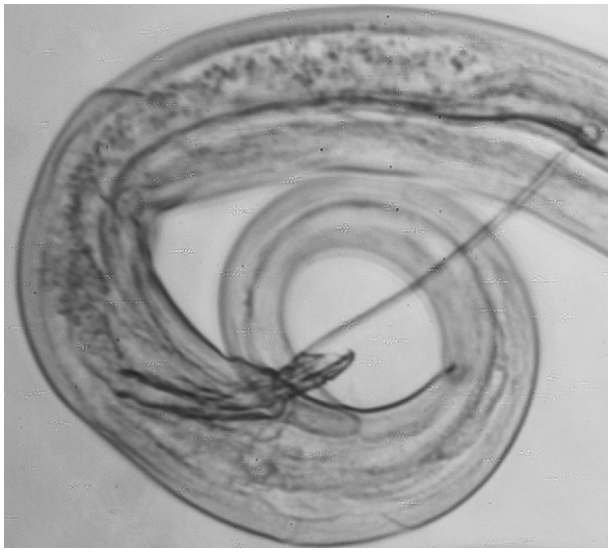

Figure 25 Posterior end of the filaroid nematode *Litomosoides* from *Ctenomys opimus* from high-altitude western Bolivia. Note the dimorphic nature of the spucules in this species one being long and filamentous the other being short and stubby.

The Science of Nematode Diversity

Nathan A. Cobb, one of the first scientists in North America to advance nematology, was a student of the renowned German zoologist, Ernst Haeckel. After just a few years of research spanning the globe from Europe, Australia, and North America, Cobb amassed a huge amount of knowledge and came to have a deep appreciation of the immense number of species that existed. With scientific knowledge based on keen observational skills, he understood the nature of both the great numerical density and species diversity of nematodes in all habitats of the globe that he examined. Thus armed, he wrote the following:

> *"In short, if all the matter in the universe except the nematodes were swept away, our world would still be dimly recognizable, and if, as disembodied spirits, we could then investigate it, we should find its mountains, hills, vales, rivers, lakes, and oceans represented by a film of nematodes. The location of towns would be decipherable, because for every massing of human beings there would be a corresponding massing of certain nematodes. Trees would still stand in ghostly rows representing our streets and highways. The location of the various plants and animals would still be decipherable, and, had we sufficient knowledge, in many cases even their species could be determined by an examination of their erstwhile nematode parasites.*

> *We must therefore conceive of nematodes and their eggs as almost omnipresent, as being carried by the wind and by flying birds and running animals; as floating from place to place in nearly all the waters of the earth; and as shipped from point to point throughout the civilized world in vehicles of traffic."* (From Cobb (1914).

As if challenged by this assertion, scientists have tested Cobb's hypotheses by examining the extremes of the biosphere on earth to evaluate the limits of nematode life. Through these investigations, biologists have now shown that nematodes are living and reproducing everywhere on Earth

Table 1 Numbers of common nematode infections in humans worldwide

Species of Nematode	*Numbers Infected*	*Distribution*
Ancylostoma duodenale and *Necator americanus*	1,298,000,000	World-wide
Ascaris lumbricoides	1,472,000,000	World-wide
Brugia maylayi and *B. timori*	13,000,000	South Pacific, SE. Asia, India
Dracunculus medinensis	80,000	Sub-Saharan Africa and Yemen
Loa loa	13,000,000	West and Central Sub-Saharan Africa and Yemen
Onchocerca volvulus	17,660,000	Central and South America and Sub-Saharan Africa
Strongyloides stercoralis	70,000,000	Temperate regions
Trichuris trichiura	1,049,000,000	World-wide
Enterobius vermicularis	400,000,000	Temperate regions

Source: Data from Crompton DWT (1999) How much human helminthiasis is there in the world? *Journal of Parasitology* 85: 397–403.

that water exists in a liquid state even for short periods of time annually.

Diversity of Habitats and Distribution

General

The most obvious ecological character that defines habitats for members of the phylum Nemata is that they all are aquatic animals – to move, live, eat, and reproduce, nematodes must exist in an aqueous environment. This environment includes soils, muds, sands, plants, and animals. They can be found living in soils with moisture contents as low as 5–10%, but in the majority of these cases, the nemas are associated with the roots of plants. It is evident that the environment in which nematodes live constrains their ultimate size. Soil dwelling species live in the water film of the interstices of soil particles. Nematodes, must live and carry out all functions of life in these spaces, thus free-living, or plant-parasitic soil-dwelling forms are usually extremely small. Morphological diversification of nematodes can operate only within the constraints of their life-history parameters, and thus, evolutionary pathways for nematodes living in an interstitial – soil or sediment/sand envionment are limited. Thus these forms have limited abilities to diversify into the nonaquatic regions of the earth, and their size is constrained by this fact.

In contrast to the small sizes of plant-parasitic, free-living marine, freshwater, or soil nematodes (some adults can be as small as (*Criconemoides*) with an adult length of around 250 μm), species that occur as parasites of animals are free from the physical constraints on their size and the bodies of species in mammals are, therefore, relatively large. In fact, the largest nematode thus far recorded is *Placentonema gigantissima* from the blue whale with a length of more than 8 meters (Maggenti, 1981). The ratio between the smallest adult nematode to the largest can be calculated as (0.250 mm (*Criconemoides*)/8,000 mm (*Placentonema*) = 0.000031), compared to the ratio between a shrew and a blue whale (50 mm/24,4000 mm = 0.12), indicating that the size differences in nematodes are three orders of magnitude greater than the mammals.

In the marine-benthic environment Lambshead (1993) has estimated (based on transect data from deep sea benthic samples) that there may be as many as 100 million species of marine infaunal nematodes. As exorbitant as that estimate seems, deep-sea nematodes have been show to be extremely rich in species diversity. One marine sediment sample from the east-Pacific benthos was reported to contain 148 species from a total of only 216 individual specimens examined (Lambshead 1993). At the present time the true extent of species diversity in the marine benthos can only be imagined because fewer than 20 studies of nematode community structure from marine-benthic habitats have been reported (Boucher and Lambshead, 1995). Relatively recent data from Boucher and Lambshead, 1995 shows that in marine environments the highest diversity in nematodes occurs in abyssal benthic sediments.

We now know that great numbers of individuals and species of nematodes live in sediments on the ocean floor distributed from the intertidal continental margins to the benthos of the abyssal zones, even though these marine habitats remain unexplored. Nematodes occur in tissues and organs of all species of vertebrates that have been studied and some, such as *Physaloptera spp*. live, feed, and reproduce in the strongest stomach acids of mammals, birds, and reptiles. Dessicated specimens from both the Arctic and Antarctic have been rehydrated to form viable colonies and living nematodes have been found in the limited meltwater in some of the dry-valleys of Antarctica, an area that is probably one of the most extreme biotopes on the earth.

Extreme Biotopes

Some of the most extreme soil habitats on the Earth exist in the Dry-Valleys of the Antarctic where the annual mean air temperature is −20 °C, and soil temperatures at a 5 cm depth for the two "summer months" range from −2.7° to 15.9 °C. In this area, no vascular plants grow and mosses and lichens are rare; this is the only terrestrial soil-system known where nematodes are the final consumers and are at the apex of the food chain (in this case it seems more of a chain than a web). Three nematode species exist in these dry soils, *Scottnema lindsayae*, a microbivore (feeding on bacteria and yeast), *Plectus antarcticus* (a bacterial feeder), and *Eudorylaimus antarcticus*, an omnivorous predator that presumably feeds on individuals of the other two species (Powers *et al*., 1998). In another biological extreme, Death Valley in California has recorded some of the highest temperatures in North America and the soils of the valley are teeming with nematodes, many of which have been discovered to possess similar adaptive traits to those found in the cold deserts of Antarctica.

Individuals of some species of Nemata are capable of resisting extended periods of dessication, for example, 3rd stage juveniles of *Anguina tritici* have been dried for more than 20 years in a state of anhydrobiosis in which all metabolic activities are shut down (Maggenti, 1981). These nematodes have been shown to have specialized proteins that fold into stable/preserved structures as the organism dries. In this state of crypto or anhydrobiosis, individual nematodes can remain viable through incredible extremes of temperature, desiccation, hypoxia, and even synthetic nematicides designed to kill nematodes (of course the regular biochemical processes that nematicides interfere with are not operational, so the nematode does not notice this particular assault). When water again becomes available, the animal in fact comes back to life when the molecular structures rehydrate and the proteins and enzymes spring back into normal operation.

Habitat Diversity

Nematodes occupy every conceivable life-history niche. There are benthic deep-water marine forms that appear to consume mostly diatoms and others such as species of the genus *Draconema* (**Figures 5(a)**, **6**) that are mostly associated with marine algae, but it is still unclear what they actually eat. Nematodes of the genus *Dirofilaria* live in the aorta and left ventricles of canids and are transmitted by mosquitoes from dog to dog. Species of nematodes live in the hearts of sharks,

and other species occur by the thousands weighing more than one kilogram in the stomach of a pilot whale (SLG pers. obs.), and, as the human consumption of raw marine fish (ceviche and sashimi) has increased, transfer of juvenile *Anasakis, Terranova,* and other anasakines from the fish intermediate host to humans is occurring more commonly and these nematodes are turning up as parasites in the stomach of humans.

Some species feed on fungi in the soil whereas others are trapped and are themselves consumed by different species of fungi. Still other nematodes like *Mononchus* (**Figure 1(b)**) and *Clarkus* (**Figure 16**) are predatory and hunt and eat other nematodes in the soil environment. Free-living bacterial feeding nematodes have been shown to be integral parts in the carbon and nitrogen cycles in healthy soils (Ferris *et al.*, 1998) and recent survey work has shown that undisturbed or natural soils in noncultivated habitats can have as many as 20 times more species than soil from similar areas that have been under cultivation (Al Banna and Gardner, 1996).

Abundance – Estimates and Facts

In addition to the large numbers of species that may occur in any given habitat, nematodes also occur in very great densities, for instance, in sheer numerical density of individuals in any given habitat, nematodes exceed even the mites and beetles combined. More than 90,000 nematodes were recorded from a single decomposing apple, and one report showed 1 cc. of marine mud contained 45 nematodes representing 19 species. Nematodes in marine estuaries occur at high numerical densities with reports of 4,420,000 m^{-2} in surface mud and 527,000,000/acre in the top 3 inches of sand in the Massachusetts coast. Counts and extrapolations for relatively moist soils (10–70% moisture content) worldwide show that in the uppermost levels, nematodes occur in mind boggling abundance: 7–9 billion/acre in undisturbed sod in North China; from 800,000,000 to >1 billion per acre (representing just 35 species), in Utah and Idaho and around 3 billion per acre in low-lying alluvial soils of Europe and other areas of North America.

How do Nematodes Affect the Biosphere?

Because of the huge numbers of nematodes that have been shown to occur in plants, animals, soils, and the benthos, there has been much speculation about the role of nematodes in basic biological processes occurring in the soils of the earth. Cobb (1914) speculated that some nematodes "are beneficial" however he also noted that this area of study of this was still in its infancy. In fact, in 2000, this area of study is still just developing and recent work has shown that nematodes can be good indicators of biodiversity (Bongers and Ferris, 1999). Gardner and Campbell (1989) showed that mammalian parasites with complex life cycles may serve as excellent indicators of areas of high biological diversity. Because of the multifarious nature of parasitic nematodes in mammals, it is expected that these kinds of species may provide biologists with additional tools for identification of areas of high biological diversity.

The fact that parasitic nematodes occur in such high prevalence and numerical densities in mammals should give us pause, there is obviously a huge energy drain on any population of mammal that we should care to analyze, and this energy drain probably causes significant decreases in the number of offspring in any given population over long periods of time.

Soils and Plants

Recent studies indicate that nematodes play a substantial role in the cycling of carbon and nitrogen in the soil environment (Bongers and Ferris, 1999) and it has been shown that the numbers of bacterial feeding nematodes increases as the bacteria increase with annual warming of the soils. In the rainforest of Cameroon, average nematode abundances of $2.04 \times 106/m^2$ of rainforest soil were found indicating that these nematodes play a significant role in carbon flux (CO_2 and CH_4) in this rain forest site (Lawton *et al.*, 1996).

Nematodes occur in, on, and around the roots, bulbs, rhizomes, stems, and leaves of plants. They can cause galls in both the somatic and germinal tissues of the plants, where the nematodes can encyst, and dry, waiting for the next stage in their life cycle. There are species that are almost fully endoparasitic, exiting the plant root or stem only as juveniles. Others are fully ectoparasitic, such as species of *Xiphinema* (the vector of grape fan-leaf virus). Some species spend part of their life-cycle in a plant and part of it in the soil. As mentioned earlier, seed parasites of the genus *Anguina* may spend most of their existence as juveniles in a dried state, the nematodes rehydrating, molting and then as adults crawling up the outside of the plant during periods of high relative humidity and then laying eggs in the seed head. The seeds are consumed by the developing juveniles, and when they dry, the seed coats protect the also dried nematodes within, and are distributed through the environment as are normal seeds (Maggenti, 1981). Nematodes of the genus *Pratylenchus* use their spear to move through the roots of the plants that they infect, penetrating the plant cells with repeated jabs of their stomatal armature.

Predators, Entomopathogenic Forms, Fungal, and Bacterial Feeders

Many nematodes that are found in the soil are either predaceous forms eating other nematodes, or forms that prey on mites, or other soil macro-organisms. The more spectacular predators such as *Mononchus* and *Clarkus* have specialized buccal structures with which to puncture the cuticles of other nematodes (**Figures 1(b)**, **16**). Microbivorous fungal and bacterial feeding nematodes are also extremely abundant with species specializing in their feeding habits on bacteria, fungi, diatoms, and other microscopic organisms. Some, such as juveniles of species of the genera *Heterorhabditis* and *Steinernema* carry special bacterial for the genus *Photorhabdus* in their digestive system. The 3rd stage juveniles wait in the soil until an unwary insect passes nearby, the nematode then homes in on and penetrates the hapless insect, making its way into the hemocoel where it releases the bacteria, which proliferate, killing the host. The nematode then feeds on the

bacterial colony and reproduces in the insect, eventually again producing 3rd stage juveniles, which leave the carcass of the insect and disperse into the soil, waiting there for another insect to invade (for more specific details of the lifecycle of these entomopathogenic nematodes see Gaugler and Kaya, 1990).

Bacterial feeding forms occur in the soil in extremely high numbers. In soils that have not been disturbed, and have a good layer of organic matter, large numbers of all kinds of nematodes occur. One of the most well-known groups is the Rhabditida or the rhabditid nematodes. These forms feed on bacteria and yeasts growing in the soil, and are typically found in high numbers in moist soils with high organic content. The most famous of these forms are members of the genus *Caenorhabditis* of which the complete genome of *C. elegans* has recently been sequenced.

Aquatic and Marine Nematodes

This is an area that is wide open for future biologists. How do the trillions upon trillions of individuals and the millions of species that occur in the oceans really affect the biosphere? Nothing is known on the subject at the present time.

How many Species of Nemata?

Estimates of Number Described

Estimates of the numbers of species of nematodes that are known (i.e., described species) vary widely. However, in 1819, Rudolphi summarized what was known of the nematodes and he recorded 11 genera and about 350 species. Just 115 years later in 1934, Filipjev reported that 4601 species of nematodes had been described with about half free-living and the other half parasitic. By 1950, Libbie Hyman estimated that approximately 9000 species were described (based on her analysis of the Zoological record with descriptions being recorded at a rate of about 200 new species being described per year). In 1981, Maggenti's summary showed around 15,000 described species. The author's analysis from counting additions to the Zoological Record shows that in a 5 year period from 1992 to 1996 numbers of descriptions were relatively stable with approximately 776 new species described (average of approximately 155 descriptions per year). From 1996 to 1998 the numbers of descriptions decreased to 118 per year, most likely due to the continued retirement and expiration of taxonomists.

How Many Species of Vertebrate Parasitic Nematodes Exist?

All species of vertebrates examined thus far serve as hosts for at least one species of parasitic nematode. Some mammalian hosts harbor many species of nematodes that are distributed through several orders and families. Some of these nematodes are highly host-specific, surviving and reproducing successfully only in host individuals comprising a single species or perhaps a closely related group of species. Other nematodes show less specificity, being much more likely to jump from one suitable vertebrate host to another during opportune times during their life-history (Brant and Gardner, 2000).

Within a host, many different types of habitats may be occupied by nematodes. As a species, *Homo sapiens* harbors around 35 species of host-specific parasitic nematodes (Chitwood and Chitwood, 1977). To illustrate the diversity of habitats in a single animal host, humans will be used as an example. In a human, nematodes can occur as juveniles in muscle tissues, usually smooth muscle like the diaphragm or the tongue (*Trichinella*), in the mucosa of the intestine (*Strongyloides*), as migrating forms in blood, and lungs (*Ascaris*), in blood or lymph as microfilariae (Filarioids of humans), as adults in the small and large intestines (*Ancylostoma*, *Necator*, *Ascaris*), as adults in mesentaries and subcutaneous tissues (*Onchocerca*, *Loa*, *Wuchereria*) and *Enterobius* in the large intestine and cecum.

Cobb was well acquainted with animal parasitic nematodes, and his familiarity with host-specificity in the Nemata led him to estimate that as early as 1914, well over 80,000 species of nematodes would eventually be found parasitizing vertebrates alone. Similar estimates could be derived for parasites of invertebrates and plants resulting in totals of free-living and parasitic species numbers far in excess of the approximately 27,000 species of nematodes known today.

> Cobb (1914) stated *"There must be hundreds of thousands of species of nematodes. Of this vast number only a very few thousand have been investigated, and of these, comparatively few with any degree of thoroughness."*

Present estimates are that only approximately 14,000–16,000 species of parasitic nematodes have been described from all taxa of slightly more than 48,000 currently recognized species of vertebrates. In addition, many species of wild mammals each harbor more than two host-specific species of nematode so the above estimate of 8900 species of nematodes only from mammals can be considered very low.

As of this writing, the natural history, development, and transmission parameters of only around 561 speceis are known (Anderson, 1992). As parasites of only vertebrates, Anderson (1992) estimated that there were about 2300 described genera distributed among 256 families comprising about 33% of all nematode genera known. This percentage is approximately equal to the percentage of genera of Nemata presently known in marine and freshwater habitats. It is agreed by most workers that this bias is due to the larger number of parasitologists working on selected groups of Nemata relative to the number of specialists working on the free-living marine and freshwater forms.

If each of the approximately 4450 known species of mammals were infected with only two species of host-specific nematodes, we would expect to find a minimum of 8900 species of parasitic nematodes only in the Class Mammalia.

Pinworms, nematodes of the Order Rhabditida Superfamily Oxyuroidea (**Figure 1**) show high levels of host specificity and it is well-known that almost all species of rodents and primates have one species-specific pinworm, (for instance, *Homo sapiens* harbors *Enterobius vermicularis*). Both recent and historical studies have shown that pinworm nematodes exhibit high levels of coevolution, i.e., concomitant host-parasite

speciation (and host-specificity) with their primate and rodent hosts (Hugot, 1999). At the present time, slightly more than 716 species of Oxyuroidea have been described with the vertebrates hosting about 496 species and invertebrates about 217 species. The greatest diversity in the Oxyuroidea to be found in the future is expected to come from examination of the Arthropoda especially beetles, cockroaches (4000 species described and more than 20–30,000 expected to be found) and millipedes (17,000 species described and more than 60,000 species expected to be found). This gives huge numbers of pinworms occurring just in the cockroaches and the millipedes if each species harbors its own species of pinworm. At least two species of pinworms (genus *Thylastoma*) occur in laboratory colonies of *Periplaneta americana* and more are expected to be found in free-living populations (J. P. Hugot, personal communication).

When adequate surveys are completed, large numbers of species of Oxyuroidea are also expected to be described from Neotropical rodents of the family Muridae. Up to the present time, only around seven species of pinworms have been described from Neotropical murids and these rodents potentially host from 400 to 800 undescribed species of Oxyuroidea, (given that only one to two new species of Oxyuroid nematode is found in each species of rodent examined). J. P. Hugot, personal communication.

Recent comparative studies in the Oxyuroidea of rodents shows that the larger the body-size of the rodent, the larger the body size of oxyurid nematodes that it harbors (Morand, *et al.*, 1996).

Comparative Nematode Diversity of New World Subterranean Rodents Geomyidae

Papers on nematode parasites from rodents of the Nearctic family Geomyidae covering the dates from 1857 to the present were reviewed. Combined with field-collected specimens from the early 1970s up to the present time, the author discovered that six of the approximately 11 nematode parasites reported from pocket gophers in North America, are host specific to only the Geomyidae (**Table 2**).

Of members of the vertebrate Class Mammalia, one of the most complete sets of nematode parasite data exists for rodents of the family Geomyidae. Of the approximately 35 known species of pocket gophers (Wilson and Reeder, 1993), at the present time only 15 species have been surveyed for parasitic nematodes. From those 15 species, six species of nematodes are known to be host-specific only to geomyids. Some nematodes such as the strongylid *Ransomus rodentorum* and the heligmosomid *Heligmosomoides thomomyos* and filarioids of the genus *Litomosoides* have been reported from more than one species of gopher, other nematode species such as *Vexillata vexillata* occur only in gophers of the tribe Thomomyini (genus *Thomomys*) but do not appear to be host-species specific.

These mammals occur in an extremely wide and ecologically variable geographic area (from southern Manitoba and British Columbia south to extreme northern Colombia) therefore, there may be many more undescribed or undetected species of nematodes in these hosts than this analysis provides. In addition, no studies on genetic diversity of nematodes (or any endoparasites) in these rodents have been published, therefore, levels of genetic variation in these nematodes are unknown and the true genetic diversity that exists will probably cause an increase in the number of nematode species that are recognized.

There is little if any evidence of phylogenetic coevolution of the nematode parasites and their pocket gopher hosts. However, all species listed are specific to species of the family Geomyidae and both *Litomosoides* and *Vexillata* appear to exhibit some level of phylogenetic host specificity with two closely related North American species of *Litomosoides* being found only in geomyids (Brant and Gardner, 2000) and species of *Vexillata* occurring more generally in members of the Geomyoidea.

Table 2

Nematode species	*Classification and Location in Host*
	Sub-Phylum Adenophorea
Trichuris fossor	Cecum and large intestine
	Sub-Phylum Secernentea
Ransomus rodentorum	Cecum/small intestine
Vexillata vexillata	Duodenum
Vexillata convoluta	Duodenum
Heligmosomoides thomomyos	Duodenum
Litomosoides thomomydis	Mesentaries
Litomosoides westi	Mesentaries

Nematodes of Tuco Tuco's (Ctenomyidae)

A review of the nematode parasites occurring in Neotropical rodents of the genus *Ctenomys* indicates a considerably more depauperate fauna of nematodes as compared with the nearctic Geomyidae (**Table 3**). Data collected from 1984 up to the present time indicate that nematodes of the genera *Trichuris* and *Paraspidodera* have cospeciated with their hosts and exhibit different levels of phylogenetic congruence relative to their hosts. In addition, nematodes of the trichostrongyloid (O. Strongylida) genus *Pudica* were encountered only two times from the same species of *Ctenomys* in one locality (from a sample of more than 500 individuals and more than six species of hosts examined). The occurrence of *A. caninum* in *Ctenomys* appears to be a capture, as it only occurred in areas

Table 3

Nematode species	*Classification*
	Sub-Phylum Adenophorea
Trichuris (>3 spp.)	Cecum and large intestine
	Sub-Phylum Secernentea
Ancylostoma caninum (host capture in synanthropic species of rodents?)	Duodenum
Pudica sp. Host capture from Muroid rodents.	Duodenum
Litomosoides (2 spp.)	Peritoneal cavity and mesenteries
Paraspidodera (>6 spp.)	Cecum and large intestine

where dogs, humans, and ctenomyids lived in relatively close proximity (banana fields in lowland Santa Cruz, Bolivia).

Although most of the pocket gophers examined carefully generally harbor from one to several species of nematodes in the small intestine, very few nematodes are found in samples of tuco-tucos. Even though the genus *Ctenomys* contains almost 40 species, comparatively few species of nematodes have been described or reported from them. This lack of parasites in a wide-open group of mammals might be a result of rapid speciation in the mammal group with parasites failing to keep up with the speciation rate of the mammals themselves and actually loosing parasites through time; there is some evidence that the ctenomyids have speciated rapidly in their history (Lessa and Cook, 1998). The lack of a diverse fauna of nematodes in these mammals could also be due to historical accident whereby the ancestor of the ctenomyids had a low diversity of nematode parasites (for whatever reason) thus giving rise to a phylogenetic lineage of mammals lacking a diverse fauna of parasites. But why have they not picked up more parasitic nematodes from other syntopic species of mammals?

There is some evidence of host-switching in nematodes of the genus *Litomosoides* in that two species occur in *Ctenomys opimus* in high-altitude Western Bolivia, but these nematodes have not been reported from any other species of *Ctenomys* from throughout the Neotropics. Superficially this indicates a host-capture event from some other lineage of mammals (Brant and Gardner, 2000). Another example is the fact that nematodes of the genus *Pudica* found in *Ctenomys* have diverse relatives in other species of muroid rodents in South America but none in ctenomyids, leading to the conclusion that most are now found in the tucos because of host-switching events, and not phylogenetic coevolution.

Nematodes of the genus *Paraspidodera* are found only in Hystricognath rodents in the Neotropical Region and these nematodes appear to have had a long historical, coevolutionary association with ctenomyids, showing varying levels of both cospeciation and host-switching. The adenophorean whip worm genus *Trichuris* occurs in many diverse groups of rodents in the neotropics and at the present time, no analyses have been done to examine the levels of coevolution with ctenomyids.

The multifarious nature of nematode diversity in subterranean mammals in the Nearctic and Neotropical Regions requires at the minimum that phylogenetic hypotheses for each group of mammals and their nematodes be developed and then each host-group can be compared with each parasite-group. Much more detailed work needs to be paid to collecting parasites from some of the unknown species of *Ctenomys* throughout the Neotropics. The same can be said about the level of knowledge of parasitic nematodes in the Geomyidae in the northern Neotropics and southern Nearctic regions.

Molecular Diversity in the Nemata

Several molecules have been used to begin to assess phylogenetic and genetic diversity within the Nemata and the number of investigations using molecular methods to try to quantify the diversity of the nematodes is rapidly increasing (Dorris *et al.*, 1999; Blaxter *et al.*, 1998; Al-Banna *et al.*, 1997; Nielsen, 1996). However, because of the extremely large number of species that may exist, examination of levels of molecular or genetic diversity in representatives of the group as a whole can be said as just the beginning even though massive amounts of molecular data on nematodes are now literally pouring into the literature stream. The summary papers by Blaxter *et al.* (1998); Dorris *et al.* (1999); Meldal, *et al.*, 2007; Holterman *et al.* (2006); Van Megan *et al.* (2009); and Bik *et al.* (2010) indicate the utility and power of estimating the molecular–phylogenetic relationships among the Nemata using ribosomal DNA and other molecular sequence data. Initial studies of the molecular diversity within and among several lineages of the Strongylida show that the genetic diversity among these taxa is relatively low (Chilton *et al.*, 1997). From these works, it is clear that molecular phylogenies will provide robust tests of the hypotheses of morphological relationships among the Nemata. As more regions of DNA are used to examine the relationships among the nematodes, we expect additional clarification of both the deep phylogenetic branches (Bik *et al.*, 2010) that are at present relatively obscure in the molecular phylogeny of the Nemata and the more rapidly evolving branch tips that represent extant species with valuable genetic information

Relationships to other Animal Groups

A recent analysis grouped the nematodes, gastrotrichs, priapulids, kinorhynchs, and the loriciferans into a group (superphylum) called the Cycloneuralia (**Figure 26**) based on the circular shape of the brains in these groups (Nielsen *et al.*, 1996). The aforementioned study and at least one other (Zrzavy, 1998) using 18s rDNA sequences showed that the Nemata share a common ancestor with members of the phylum Nematomorpha but there was a shuffling of the other groups out of the "Cycloneuralia" (**Figure 27**).

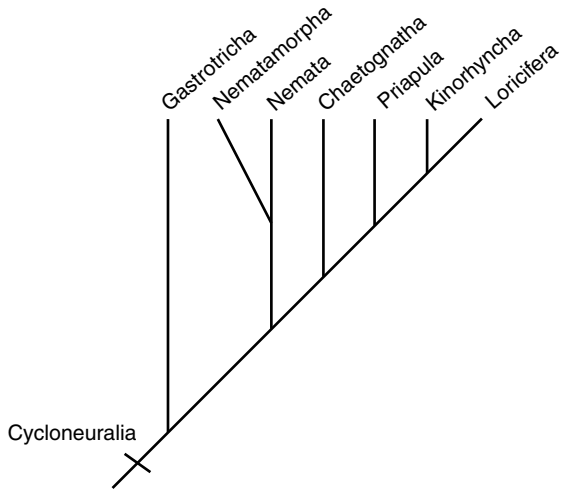

Figure 26 Phylogenetic tree showing the relationships of the Nemata to the rest of the Cycloneuralia.

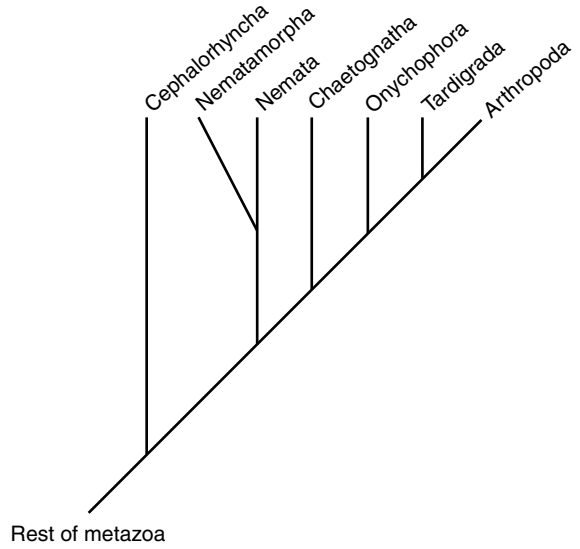

Figure 27 Phylogenetic tree showing the relationship of the Nemata to the rest of the Animalia.

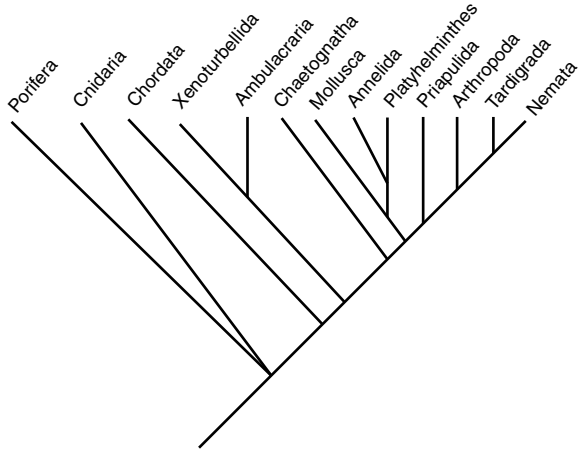

Figure 28 Phylogenetic tree of the Bilateria showing the sister group of the Nemata to be members of the phylum Tardigrada or the moss bears.

More recently, Lartillot and Philippe (2008) presented a molecular phylogeny of the Bliateria where they show the Nemata as sharing a most recent common ancestor with members of the phylum Tardigrada and are close to the phylum Arthropoda in their final tree (**Figure 28**).

As mentioned above, nematodes are soft-bodied and mostly very small organisms, any larger forms that existed in prehistory were probably parasites of vertebrates, however, these left no fossil traces. The only fossil nematodes that are known are insect parasitic or plant parasitic forms that occur very rarely in amber inclusions, but these are also not very old. Because there are no fossil records of nematodes of Cambrian or Precambrian ages, estimates of the age of the Nemata have been only speculation up to the present time and without fossils; it is difficult to calibrate molecular clocks for the nematodes. However, through application of various models of molecular evolution and molecular clock theory, estimates of the time of divergence of the nematodes from the rest of the animal groups appear to be approximately 1177–1179 million years (Wang *et al.*, 1999) (this study showed a basal origin of the nematodes on a phylogenetic tree, in contrast to the relatively derived placement in the analyses shown in **Figures 26–28**).

Most authors consider that nematodes arose from a Marine ancestor. The tri-radiate esophagus and the tubular body indicate a possible primarily sedentary existence with the posterior end attached to the substrate and the anterior end freely encountering the marine environment from all sides, thus the secondarily derived somewhat radial symmetry (Maggenti, personal communication).

Classification and Groups of the Nemata

Above the level of the order, confusion reigns relative to the classification and systematic arrangement of the nematodes. Maggenti (1991) is usually followed in this regard and his analyses followed corroborated historical analyses in recognizing the two main sub-phyla: the Secernentea and the Adenophorea. Recent work shows that these groups are substantiated both in morphological and molecular analyses although competing phylogenetic hypotheses and associated classifications have also relatively recently been proposed (Dorris *et al.*, 1999; Blaxter *et al.*, 1998; Adamson, 1989). Even more recent work by Meldal *et al.* (2007); Holterman *et al.* (2006); Van Megen *et al.* (2009) and Bik *et al.* (2010) have provided some larger scale analyses of the Nemata using sequencing of ribosomal DNA and other conserved genes.

A systematic treatment of the nematodes was recently undertaken by Hodda (2007) where he reviews the systematics of the group and proposes a classification that incorporates molecular, developmental, and morphological advances. He reviews the classification of the Nemata as a phylum (although he uses Nematoda as the name). Here the author would like to point out that Maggenti (1981, 1991a, and 1991b) used Nemata as the name for the phylum as he often pointed out that "Nematoda" is a class level name left over from the old classification when nematodes were considered a class in the phylum Aschelminthes. If the nematodes were considered a class under a different phylum name, then Class Nematoda would be appropriate, as it is, Phylum Nemata is more correct (A.R. Maggenti, personal communication).

Since 1949, at least eight authors have provided classifications for members of the phylum Nemata (Malakhov, 1994; Brooks and McLennan, 1993; Maggenti, 1991). Of these, the classifications of Maggenti (1981; 1991) have proven to be the most useful summary of all nematodes (free-living, and parasitic); however, phylogenetic hypotheses have recently been proposed based on both molecular and morphological characteristics. This does not necessarily mean that because a phylogeny has been proposed that a classification from that phylogenetic tree will result (Maggenti, 1991a and Brooks and McLennan, 1993).

At this point in time, the synthetic classification proposed by Hodda (2007), which takes the arrangement down to the level of the family, appears to be the most easily useable and informative new classification. He presents the groups in a

table format, and as noted above, uses information from many different fields of study of the Nemata to generate the classification. One of his goals was to minimize the changes in taxonomic rank of well established groups to achieve stability and he generally follows the use of superorders (e.g., Maggenti, 1991).

Future Knowledge of Nematodes

The author hopes that this summary treatment provides readers with sufficient knowledge to allow more in-depth research on nematodes. The group is so large, and so ecologically, morphologically, and phylogenetically diverse that to attempt to discuss the diversity of the group in such an abbreviated way is practically futile at best. N. A. Cobb (1914) stated this clearly on the last page of his famous "Nematodes and Their Relationships" (pp. 490).

> *"The foregoing fragmentary sketch may indicate to the student, as well as to the general reader, the vast number of nematodes that exist, the enormous variety of their forms, and the intricate and important relationships they bear to mankind and the rest of creation."*

As more data on distribution and function of nematodes throughout the biosphere are obtained, the importance of this group of worms will surely be realized. We are just beginning to explore the oceans, and we are probably losing more species of nematodes from rainforest clearing than will ever be ultimately found, described, and classified.

The author hopes that mankind will generate more interest in the microscopic world of the Nemata, and that this section will provoke the reader into action and disprove what Van Leeuwenhoek stated about his fellow man on 28 September, 1715 in which he said: "...And over and above all, most men are not curious to know: nay, some even make no bones about saying, What does it matter whether we know this or not?" (Dobel, 1932; pp. 324–325).

Acknowledgments

Glossary

Acetabulum Ventral sucker used for attachment and locomotion in digeneans.
Acoelomate Lacking a body cavity; see parenchyma.
Cercomer Posterior parenchymous or muscular extension of body; homology among groups is controversial; some view both the hook-bearing regions of monogeneans and some larval cestodes to be modifications of the cercomer.
Cirrus Male intromittent copulatory organ consisting of distal, invaginable portion of ejaculatory duct that is evaginated (by turning inside out) through the genital pore during copulation; may or may not be armed with spines, microtriches, etc.; see penis.
Cortex The outermost region of parenchyma in taxa in which two distinct regions are present; inner boundary often marked by conspicuous circular muscle fibers; see medulla.
Duogland adhesive system Combination of a cement, a viscid gland producing adhesive material, and a releasing gland; usually associated with cells of ventral epidermis; provides temporary adhesion to the substrate for many interstitial flatworm species.
Gonochoristic Individual organisms exhibit only one of two sexes.
Haptor The posterior attachment organ of monogeneans.
Hermaphroditic Individual organisms exhibit both sexes.
Medulla The innermost region of parenchyma in taxa in which two distinct regions are present; outer boundary often marked by conspicuous circular muscle fibers; see cortex.
Microthrix A specialized surface extension of the neodermis of cestodes, characterized by an electron-dense cap composed of numerous cap tubules separated from a core of distal cytoplasm by a baseplate (plural microtriches); aid in attachment and possibly absorption of nutrients.
Monozoic Possessing only a single set of reproductive organs; see polyzoic.
Neodermis A syncytial, nonciliated epidermis with cell bodies and nuclei (often referred to as cytons or pericaryon) laying below other body wall elements; unique to the Neodermata; completely replaces epidermis, usually at metamorphosis when larva encounters the first host.
Parenchyma The connective tissue between cells of ectoderm and endoderm layers that fills spaces among organ systems; as platyhelminths are acoelomates, the space among internal organs is completely filled with parenchyma.
Penis Male intromittent copulatory organ consisting of a muscular, often papilliform, retractable structure that is protruded (without turning inside out) through the genital pore during copulation; may or may not be armed with spines, etc.; see cirrus.
Polyzoic Possessing multiple serial sets of reproductive organs; condition found in most cestode orders.
Proglottid Compartmentalized regions of cestode body; each proglottid contains one or more sets of reproductive organs; not homologous with segments of coelomates.
Rhabdite A rod-shaped, proteinaceous secretory product found in the epidermis of most free-living platyhelminths; known functions include mucus production for ciliary gliding, cocoon formation, prey capture, and predator repulsion.
Scolex Attachment organ in adult eucestodes; often bearing suckers, loculi, or hooks.
Statocyst Static sense organ in which the movement of a statolith is detected, thereby indicating an animal's orientation.
Strobila The portion of the body of cestodes exhibiting serial repetition of proglottids.

The Phylum Platyelminthes is presently considered to contain approximately 30,000 species, although that number is likely to be a gross underestimate. These animals are usually bilaterally symmetrical, many are dorsoventrally flattened; they generally lack a body cavity and most are hermaphroditic. None of these features, however, is unique to this phylum, and thus, none can be counted on for the definitive recognition of membership in the group. That is not to say the phylum does not represent a natural assemblage of taxa. Molecular analyses support its monophyly and the platyhelminths appear to be unique in their possession of protonephridial cilia that lack accessory centrioles. Unfortunately, the latter feature can be observed only with transmission electron microscopy and thus it is not especially convenient for the casual identification of platyhelminths. In many cases, it is more useful to turn to the rather distinctive features that characterize the individual platyhelminth subgroups.

Because they lack a protective outer body covering, water figures prominently in the lives of the platyhelminths, and indeed, the majority of species are found in moist or aquatic environments. Marine, freshwater, and terrestrial environments have all been colonized, the latter to a lesser extent than the former two environments. The phylum includes species spanning a wide range of adult lifestyles, from those that are

free-living interstitial dwellers to those that are symbiotic with invertebrates or obligate (internal or external) parasites of vertebrates. Consequently, the group includes species ranging enormously in size (200 μm–80 m), shape, form, and occasionally color. Species that are obligate parasites of vertebrates belong to four distinctive, potentially monophyletic groups: Monogenea, Aspidogastrea, Digenea, and Cestoda. A number of these are of significant medical or veterinary importance. There exists little evidence to suggest that the remaining platyhelminths, many of which are free-living members of the meiofauna and some of which exist as either commensals or parasites of invertebrates, form a single cohesive group, although collectively they are often referred to as "turbellarians." Present knowledge suggests that the parasitic groups are more speciose than the nonparasitic groups. However, there is no question that numerous free-living and parasitic taxa await discovery and formal description.

General Features

A glance at the defining features of each of the major platyhelminth groups reveals that the characteristics that vary most among, and even within, these groups are primarily those associated with the digestive and reproductive systems. However, in the parasitic taxa, the features associated with attachment also vary markedly. When present, the digestive system generally lacks an anus. Thus, there is no unidirectional flow of food materials through this system; in many species food enters and solid wastes exit through the oral opening. Most platyhelminths are hermaphroditic, with each individual possessing both male and female reproductive organs. Several major features of the female reproductive system are of particular importance. The female gonads of platyhelminths are either homocellular, consisting of only a single type of cell that produces both ova and vitelline material (i.e., yolk and shell precursors), or heterocellular, consisting of two cell types, one that produces ova and one that produces vitelline materials. The former configuration results in the production of endolecithal eggs thus vitelline material is incorporated directly into the cytoplasm of the ova; the latter configuration results in the production of ectolecithal eggs, as vitelline cells are packaged along with, but independent of, the zygote in the egg. Heterocellular platyhelminths usually, but not always, conduct these functions in separate organs, often possessing one, or occasionally more, ovaries that produce ova, and a vitellarium consisting of vitelline cells that produce nutritive yolk and shell precursors.

In addition, most platyhelminths possess a formalized excretory system consisting of two (rarely one or three) sets of protonephridia, which may be connected at several points throughout the body or may join at a common excretory vesicle. The nervous system and sense organs are present to a greater or lesser extent among different taxa. Specialized organs functioning in respiration and circulation are entirely lacking in many groups of platyhelminths. Thus, respiration generally occurs by means of diffusion of gases directly through the surfaces of the body, a process that is greatly facilitated by the relatively flattened nature of the platyhelminth body. The "circulation" of materials throughout the various parts of the platyhelminth body is also accomplished by diffusion. However, a number of digeneans are known to possess a "lymphatic system" with contractile vessels and cellular inclusions that may have a circulatory function. The details of most organ systems are difficult to observe without the use of specialized staining and microscopic techniques.

One final, rather unusual feature of the platyhelminths is that the differentiated nonreproductive (somatic) cells of the body are unable to divide. Thus, mitosis does not occur in the differentiated somatic cells of platyhelminths; rather, these cells are replaced as necessary by undifferentiated stem cells located below the outer layers of the body, which undergo mitosis. This phenomenon helps to explain the remarkable regenerative abilities of certain platyhelminth groups.

Major Groups

Diversity in the platyhelminths is most effectively represented at the taxonomic rank of order (or superfamily in the digeneans). Within the phylum, this rank is relatively informative and is much more numerically manageable than lower ranks such as family or genus (i.e., there are 71 orders (or superfamilies in the case of the digeneans) versus 391 families and 3847 genera). However, it is important to recognize that traditionally, not only have taxonomists working on each of the three major groups exhibiting obligate parasitism (Digenea, Monogenea, and Cestoda) generally worked independently from one another, but they have also worked independently from the taxonomists studying the platyhelminths exhibiting more free-living life history strategies. Thus, the concepts of higher ranks, such as order, are not necessarily comparable among the major groups. For example, the 716 genera of monogeneans are currently distributed among ten orders, whereas the 1592 genera of digeneans are distributed among only three orders. Nonetheless, diagnoses are presented for orders in all groups except the digeneans, which are treated at the level of superfamily. The numbers of families and genera for each of the orders (or superfamilies in the case of the digeneans) are given in **Table 1**. This treatment reflects recent taxonomic revisions and discoveries, and thus, in addition to revised estimates of families and genera, includes two turbellarian orders, four cestode orders and eight digenean superfamilies not included in the first edition of this article. Given the lack of a recent comprehensive treatment, the numbers presented below for the monogeneans were developed in consultation with I. Whittington and D. Kritsky. The Acoela and Nemertodermatida have been removed from consideration because they are no longer considered to belong to the Platyhelminthes, rather they appear to be basal bilaterians, or possibly even early divergent deuterostomes.

For more detailed information on specific groups, readers are referred to the works of Cannon (1986), Rieger (1998), and Tyler *et al.* (2006–2010) for the non-neodermatan (i.e., free-living and invertebrate associated) groups; Yamaguti (1971); Schell (1985), and the CABI keys (Gibson *et al.*, 2002; Jones *et al.*, 2005; Bray *et al.*, 2008) for the digeneans;

Yamaguti (1963); Schell (1985) and Boeger and Kritsky (2001) for the monogeneans; and Schmidt (1986) and Khalil *et al*. (1994) for the cestodes. However, the treatments of these groups by Hyman (1951) and the five sections covering the platyhelminths in the Traité de Zoologie (Grassé, 1961) are classics and remain among the more comprehensive sources of detailed information on the platyhelminths. The many works of Klaus Rohde (e.g., 1997), Ulrich Ehlers (e.g., 1985), Peter Ax (e.g., 1996), and Tim Littlewood (e.g., 2006), among others, have done much to further our understanding of the morphology and phylogenetic relationships among these groups.

Discussions of diversity are most effectively organized around hypotheses of the phylogenetic relationships among the groups involved. Although many aspects of the phylogenetic relationships among the members of this phylum remain unresolved, the tree in **Figure 1** illustrates some of the aspects of these relationships for which supporting morphological and molecular data are starting to accumulate. The presentation of diversity that follows is generally organized around the topology of this tree. The non-neodermatan orders are treated in the sequence in which they appear from left to right on this tree; orders or superfamilies of each of the three major neodermatan groups are treated in alphabetical order. A more detailed treatment of the phylogenetic relationships among the various groups is provided in the section on Phylogenetic Relationships.

The authors have presented an illustration of a representative of each platyhelminth order (or superfamily for the digeneans). A consistent stippling pattern has been used throughout these figures for each different organ system so that the conditions of the major organs are readily visible and comparable among figures and among major groups. The organs represented by each stippling pattern are labeled in Figure 9 (**Plate 1**) and Figure 28 (**Plate 3**).

"Turbellaria"

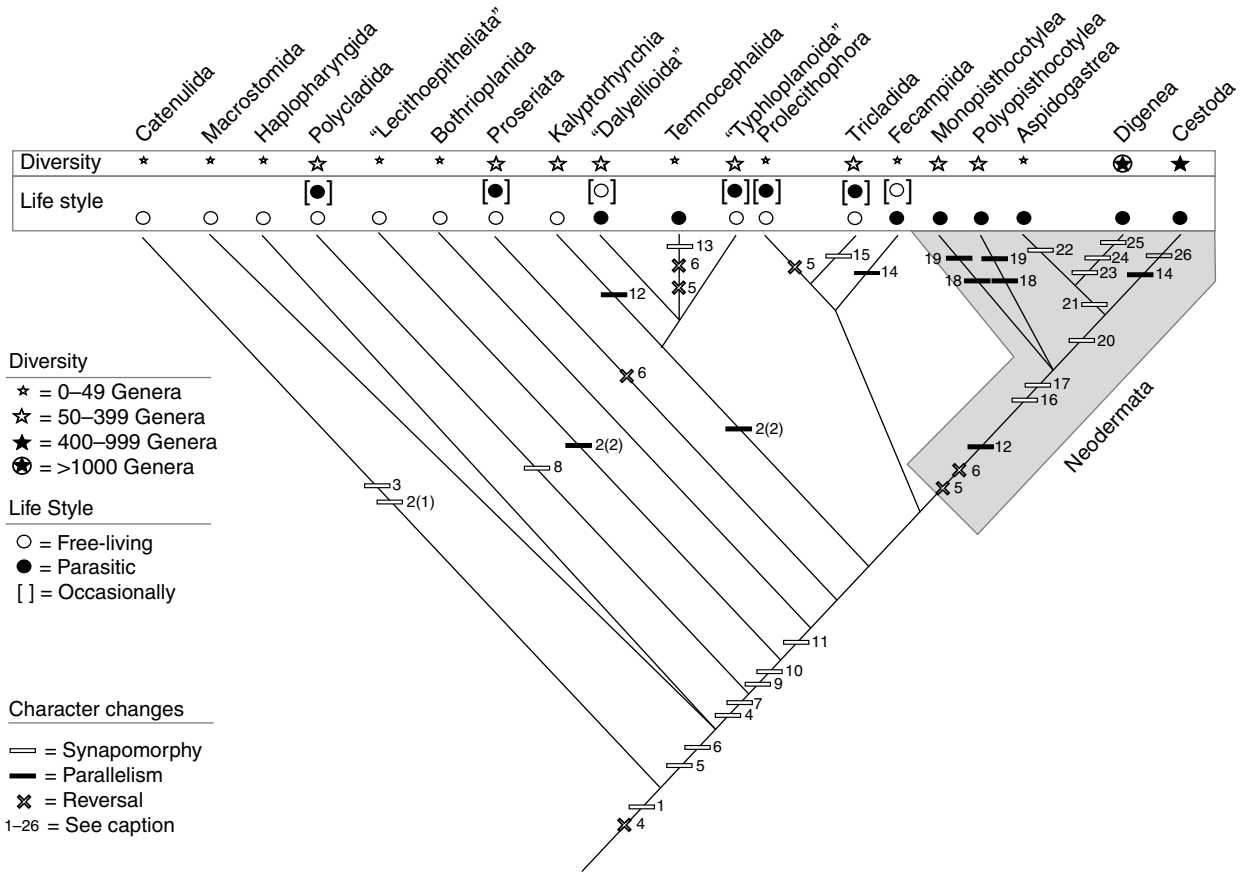
Catenulida

See Figure 2 (**Plate 1**). Some with tail; lamellated rhabdites absent, unlamellated rhabdoids present; duogland adhesive system absent; epidermal ciliation sparse, with cilia able to reverse beat; some with V-shaped ciliated oral furrow; brain lobed or not; statocyst often present, usually with one but occasionally with up to six statoliths and several parietal cells; mouth ventral, opening into simple pharynx; intestine in form of simple elongate sac; some lacking mouth and obtaining nutrients from endosymbionts in trophosome; protonephridial system unpaired; with single hermaphroditic gonad or separate male and female gonads; sperm aflagellated; penis present or absent, with common genital pore; vitellarium absent; eggs endolecithal; most undergo asexual multiplication *via* paratomy (subdivision of the body into multiple parts, each of which develops a head) or parthenogenesis (development of an embryo without fertilization).

Habitat: All species are free-living, primarily in freshwater, but some in marine and terrestrial environments.

Macrostomida

See Figure 3 (**Plate 1**). Frontal glands sometimes present; some with spatulate posterior region bearing adhesive papillae; lamellated rhabdites present; duogland adhesive system present; brain not encapsulated; statocyst absent; simple pharynx present, sometimes tubular; intestine in form of simple elongate sac, sometimes with pre-oral blind sacs; with protonephridial system paired; testes compact, single or paired; sperm aflagellated; seminal vesicle present or absent; prostatic vesicle present or absent; penis present or absent; penis stylet present or absent, female pore anterior to male



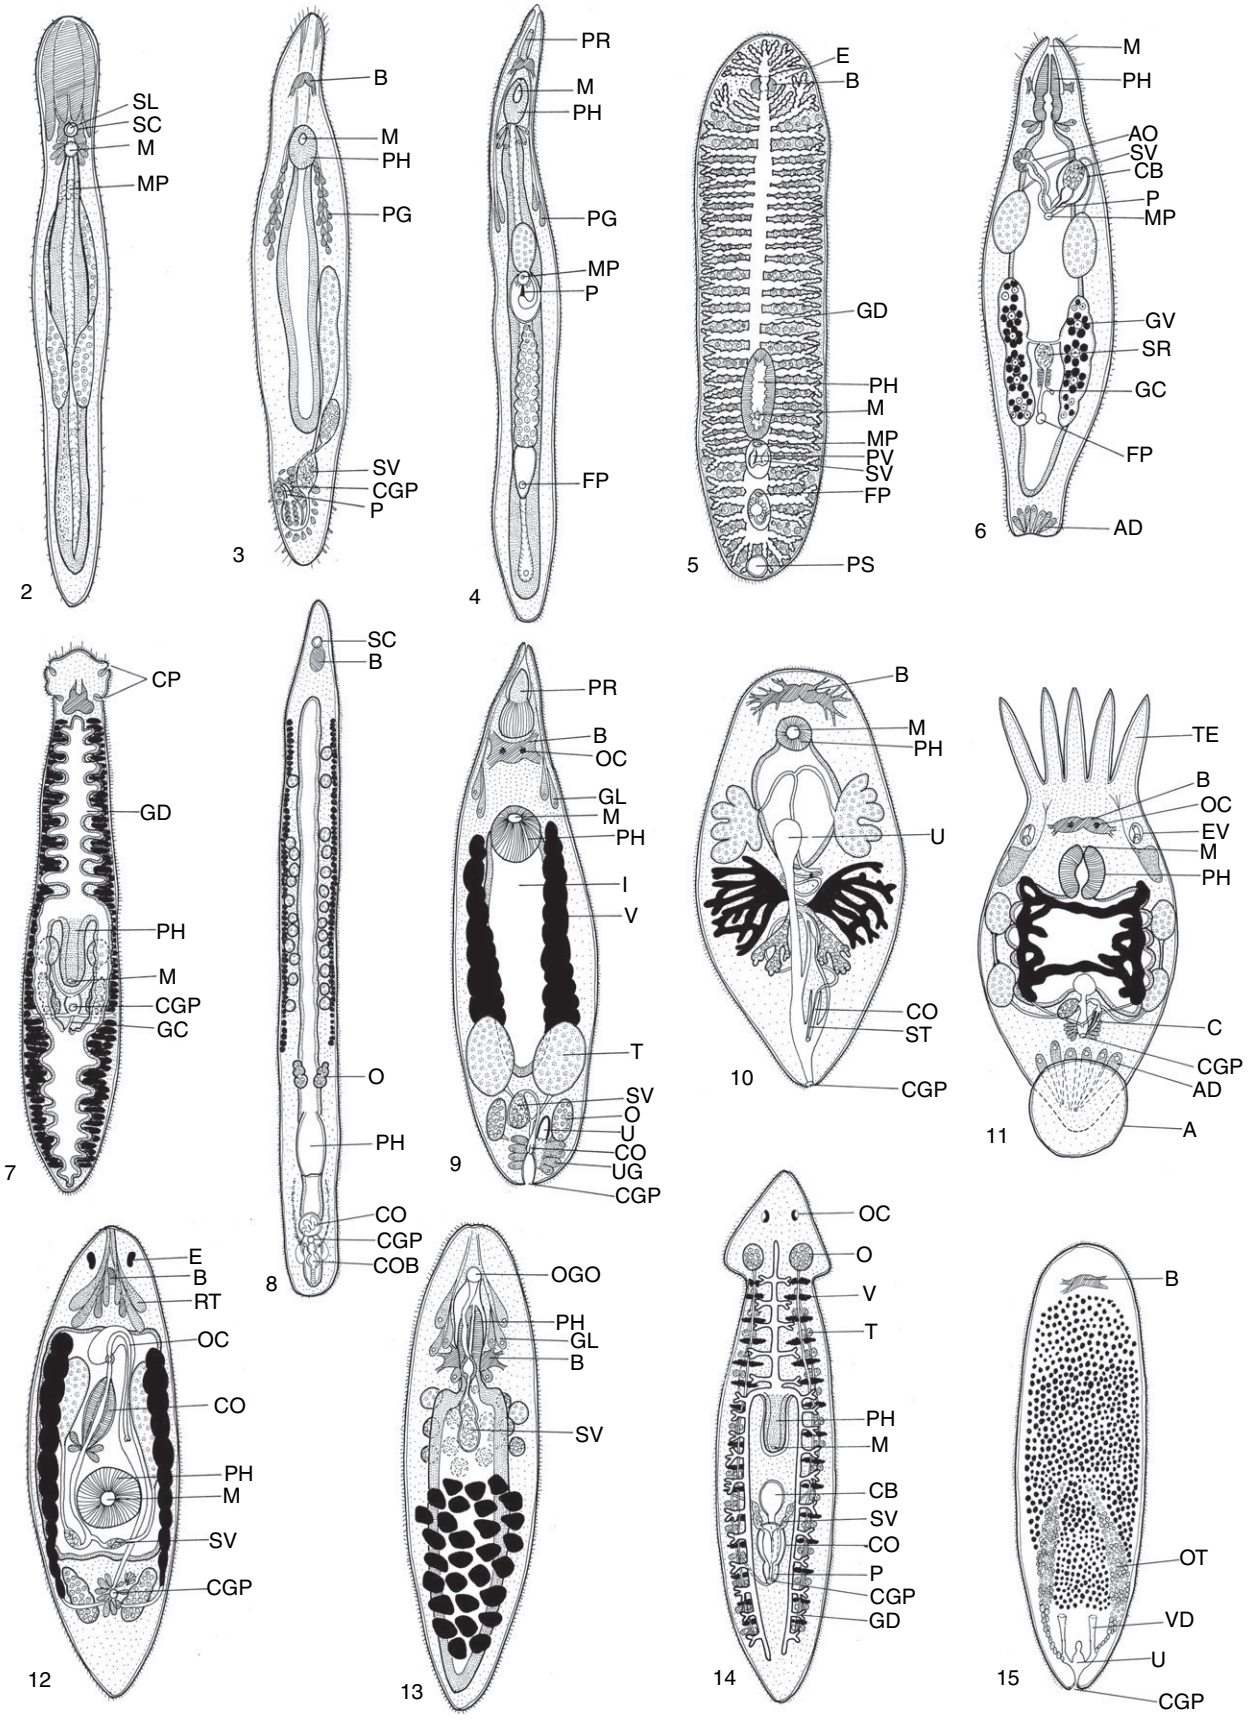


Figure 1 Hypothesized phylogenetic relationships among major platyhelminth groups. State "0" should be assumed prior to point at which character is marked on tree; state "1" should be assumed if character is marked on tree but no state is given. Solid bars indicate homoplasious characters; x indicates character reversals. Topology is synthesized from various recent molecular systematic estimates of phylogeny; where there exist no morphological apomorphies there is often consistent support from molecular data.

1. Accessory centriole in protonephridial flame bulb cilia: 0 = present; 1 = absent
2. Protonephridial type (sensu Rhode, 1991): 0 = Type 2; 1 = Type 1; 2 = Type 3
3. Protonephridial system: 0 = paired; 1 = unpaired
4. Sperm flagellation: 0 = no flagellum; 1 = biflagellated
5. Rhabdites: 0 = absent; 1 = present (CHECK distribution!)
6. Duogland adhesive system: 0 = absent; 1 = present
7. Arrangement of microtubules in sperm flagella when present: 0 = 9 + 2; 1 = 9 + '1'
8. Intestinal branching: 0 = absent; 1 = extensive
9. Configuration of female gonad: 0 = homocellular; 1 = heterocellular
10. Eggs: 0 = endolecithal; 1 = ectolecithal
11. Relationship between ovary and vitelline tissues: 0 = in same organ; 1 = in separate organs
12. Flagellum of sperm cell: 0 = not incorporated into cytoplasm of sperm cell; 1 = incorporated into cytoplasm of sperm cell
13. 2–12 anterior tentacles: 0 = absent; 1 = present
14. Digestive system: 0 = present; 1 = absent
15. Extra, embryonic intestine: 0 = absent; 1 = present
16. Form of outer body layer: 0 = cellular epidermis; 1 = syncytial neodermis
17. Epidermal cells: 0 = not shed by larva; 1 = shed by larva
18. Haptor: 0 = absent; 1 = present
19. 4 rhabdomeric ocelli at some time in their lives: 0 = absent; 1 = present
20. Complex life cycle: 0 = absent; 1 = present
21. Epidermal cells of larva: 0 = not separated from one another by neodermis; 1 = separated from one another by neodermis
22. Oviduct construction: 0 = not divided into chambers; 1 = divided into chambers
23. Miracidium: 0 = absent; 1 = present
24. Sporocyst/redia: 0 = absent; 1 = present
25. Cercaria: 0 = absent; 1 = present
26. Microtriches: 0 = absent; 1 = present

pore; ovary single or paired; vitellarium absent; eggs endolecithal; genital pores separate or combined; ability to asexually produce zooids present or absent.

Habitat: All species are free-living in marine, brackish, or freshwater environments.

Haplopharyngida

See Figure 4 (**Plate 1**). With protrusible anterior proboscis not connected to digestive system; lamellated rhabdites present; duogland adhesive system present; brain enclosed in connective tissue capsule (encapsulated), bilobed; statocyst absent; mouth opens into simple muscular pharynx; intestine in form of simple elongate sac; protonephridial system paired; single testis present; sperm aflagellated; penis present, with stylet and circle of hard, straight needles; single ovary; vitellarium absent; eggs endolecithal; with single posterior/ventral pore.

Habitat: Both species free-living in marine environments.

Polycladida

See Figure 5 (**Plate 1**). Body oval or elongate, or thick and broad with folded margins; with (Cotylea) or without (Acotylea) pseudosucker posterior to female genital pore; anterior or nuchal (neck) tentacles present or absent; ventral prostatoid-like organs present or absent; dorsal surface smooth or papillate; body margins of some with hard spines; may be multicolored with complex patterns; lamellated rhabdites present; duogland adhesive system present; statocyst absent; numerous ocelli usually present, marginal or scattered anteriorly, some arranged in one or two pairs of clusters (cerebral and tentacular), some ventral; pharynx variable in position, ruffled and vertically oriented or sometimes consisting of anteriorly directed tube, rarely consisting of multiple tubes arranged ventrally; intestine usually with numerous radiating branches, branches sometimes anastomosing, sometimes with anal pores; protonephridial system paired; testes numerous, scattered between branches of gut; sperm biflagellated, flagella not incorporated into body of sperm, $9+'1'$ microtubule arrangement; true seminal vesicle present or absent; intromittent organ absent or in form of penis or cirrus; penis stylet present or absent; cirrus armed or not; prostatic vesicle present or absent; bursa copulatrix present or absent; some with multiple copulatory complexes; ovaries numerous, dorsal to branches of gut; Lang's vesicle (possibly for digestion of excess sperm) opening into vagina present or absent; uterus present or absent (in form of expanded oviducts in some); vitellarium absent: eggs endolecithal; male and female gonopores usually separate (male anterior to female) but sometimes combined; some with hypodermic impregnation.

Habitat: Predominantly marine, a few in freshwater or brackish water; mostly free-living, some interstitial, some symbiotic with other invertebrates, for example, wrapped around the abdomen of hermit crabs, associated with gorgonian corals in mantle cavities of gastropod or lamellibranch molluscs, in genital bursa of ophiuroid or echinoid echinoderms; some live in association with their food, for example, in association with tunicate colonies feeding on zooids, or in association with oyster colonies feeding on oyster tissue; some seek shelter in empty shells.

''Lecithoepitheliata''

See Figure 6 (**Plate 1**). Some with weak posterior adhesive zone; some with pigmentation; lamellated rhabdites possibly present; duogland adhesive system present; statocyst absent; mouth anterior; pharynx variably bulbous, anterior; intestine in form of simple elongate sac; protonephridial system paired; testes compact or follicular, one or many; sperm biflagellated, flagella not incorporated into body of sperm, $9+'1'$ microtubule arrangement; seminal vesicle present or absent; penis present, usually with stylet; muscular copulatory bulb present or absent; accessory male organ present or absent, if present opening into male atrium, prostatic vesicle present or absent; male pore opening to outside or into pharyngeal cavity; female organ single or tetrapartite, in form of heterocellular germovitellarium (vitelline-producing cells surrounding ovum-producing cells); seminal receptacle present or absent; genitointestinal canal sometimes present; female pore ventral; eggs ectolecithal (yolk not produced in oocytes). The group is likely not monophyletic.

Habitat: All species are free-living in freshwater, marine, or terrestrial environments.

Bothrioplanida

See Figure 7 (**Plate 1**). With posterior papillae (i.e., *Haftpapillen*); body ciliated, with two pairs of ciliated pits; statocyst absent; pharynx plicate, posteriorly directed; gut splitting laterally around pharynx and fusing again posterior to pharynx, with lateral diverticula; with one pair of protonephridium;

Plate 1 ''Turbellaria'' (Figures 2–15) 2. Catenulida: adult of *Retronects* sp. 3. Macrostomida: adult of *Bradynectes* sp.; 4. Haplopharyngida: adult of *Haplopharynx* sp. 5. Polycladida: adult of *Cestoplana* sp. (Beauchamp in Grassé, 1961); 6. ''Lecithoepitheliata'': adult of *Gnosenesima* sp. 7. Bothrioplanida: adult of *Bothrioplanus* sp. (Beauchamp in Grassé, 1961); 8. Proseriata: adult of *Parainvenusta englarorum* (Curini-Galletti, *et al*., 2010); 9. Kalyptorhynchia: adult of *Cystiplana* sp. 10. ''Dalyellioida'': adult of *Syndesmis* sp. 11. Temnocephalida: adult of *Temnocephala* sp. (Baer in Grassé, 1961); 12. ''Typhloplanida'': adult of *Promesostoma* sp. (Ehlers, 1974); 13. Prolecithophora: adult of *Prolecithoplana* sp. (from several literature sources); 14. Tricladida: adult of *Dugesia* sp. 15. Fecampiida: adult of *Fecampia balanicola*. Abbreviations: A, adhesive disc; AD, adhesive glands; AO, accessory male organ; B, brain; C, cirrus; CB, copulatory bulb; CGP, common genital pore; CO, copulatory organ; COB, copulatory bursa; CP, ciliated pits; E, eyespot; EV, excretory vesicle; FP, female genital pore; GC, genitointestinal canal; GD, gut diverticula; GL, gland cells; GV, germinovitellarium; I, intestine; M, mouth; MP, male genital pore; O, ovary; OC, ocellus; OGO, orogenital opening; OT, ovotestis; P, penis; PG, proboscis glands; PH, pharynx; PR, proboscis; PS, pseudosucker; PV, prostatic vesicle; RT, rhabdoid tracts; SC, statocyst; SL, statolith; SR, seminal receptacle; ST, stylet; SV, seminal vesicle; T, testis; TE, tentacle; U, uterus; UG, uterine gland; V, vitellarium; VD, vitelline duct.

testes paired, compact, possibly producing only degenerate sperm; ovaries small, paired, at distal end of vitelline duct; vitellarium follicular; with single gonopore; genitointestinal canal extending from genital atrium to posterior arm of gut.

Habitat: Single known species free-living usually in freshwater environments, occasionally terrestrial.

Proseriata

See Figure 8 (**Plate 1**). Epithelial nuclei insunk or not; body of some with feeble or prominent tactile bristles; body uniformly ciliated (sometimes with exception of caudal tip) or cilia restricted to ventral surfaces and head; head with or without ciliated pits; lamellated rhabdites absent; duogland adhesive system present; brain encapsulated or not; statocyst present or absent; pigmented ocelli present or absent; pharynx plicate, tubular; intestine linear or tripartite, dorsal to pharynx; protonephridial system paired or tripled, occasionally single; testes single, paired or multiple, usually follicular, rarely compact; sperm biflagellated, flagella not incorporated into body of sperm, $9+'1'$ microtubule arrangement; usually with single male copulatory; occasionally with accessory (prostatoid) organ; bursa present or absent; with one pair of compact ovaries, ovary subdivided into smaller follicles consisting of oocytes surrounded by accessory cells in some; vitellarium follicular, follicles in paired lateral rows; vagina externa present or absent; genitointestinal canal usually present; eggs ectolecithal; genital pores common or separate.

Habitat: Free-living, predominantly in marine environments; a few occur in freshwater; occasionally ectocommensal on marine crustaceans.

Kalyptorhynchia

See Figure 9 (**Plate 1**). Body usually ciliated throughout; rarely with subepidermal spicules of crystalline calcium carbonate; rarely with anterior girdle of highly vacuolated epidermal cells; anterior sheathed proboscis usually present, divided or not, with or without hooks, gland cells, or specialized apex; lamellated rhabdites present in some; duogland adhesive system present; statocyst absent; ocelli present or absent; pharynx variable in position (anterior or posterior), bulbous, usually oriented ventrally, with or without sphincter or hard knobs, not associated with proboscis; gut usually in form of simple elongate sac; protonephridial system paired; testes single or paired, or in form of median row of follicles; sperm biflagellated, flagella not incorporated into body of sperm, $9+'1'$ microtubule arrangement; internal seminal vesicle in copulatory bulb or not; copulatory organ with stylet or not; or three separately opening prostatic organs with their own spiny cirri, or one cirrus, or copulatory organ with no penial or cirrus structures; prostate vesicle incorporated in testis or not; prostate with spiny structures or not; ovary and vitellarium separated or not (ovo-vitellarium), paired or single; uterus generally present, with or without accessory piece; seminal receptacle present or absent, paired or not; bursa present or absent; eggs ectolecithal; usually one but sometimes two gonopores.

Habitat: All species free-living, primarily in marine or brackish water, several in freshwater, environments.

''Dalyellioida''

See Figure 10 (**Plate 1**). Lamellated rhabdites present in some; duogland adhesive system absent; cilia completely covering body, or just ventral; statocyst usually lacking; paired ocelli present or absent; mouth, pharynx, and intestine present or occasionally absent; pharynx bulbous, oriented anteriorly if present; intestine in form of simple elongate sac if present; paired protonephridial system present or occasionally absent; testes paired, compact or lobed; sperm biflagellated, flagella not incorporated into body of sperm, $9+'1'$ microtubule arrangement; with or without male copulatory organ; if present male organ with or without stylet; ovary and vitellarium separate or occasionally combined; ovary single or paired, lobed; vitellarium single or paired, branched or unbranched; seminal receptacle present or absent; uterus present; copulatory bursa present or absent; single genital pore present or absent; at least one taxon is gonochoristic and sexually dimorphic (*Kronborgia*). The group is likely not monophyletic.

Habitat: Some species free-living in marine, freshwater, or terrestrial environments; many species commensal or parasitic: for example, in connective tissue of tube feet of asteroid echinoderms, in hemocoel of crabs, shrimp, amphipods, and isopods, in the mesenchyme of myzostomid annelids, in kidneys and gonoducts or mantle cavity and gut of gastropod molluscs, in stomach of lamellibranch molluscs, in mesenchyme of the turbellarian *Plagiostomum*, in either the coelom or the digestive tract of holothurioid, echinoid, or crinoid echinoderms; some also in sipunculans.

Temnocephalida

See Figure 11 (**Plate 1**). Usually with two to 12 anterior tentacles, tentacles usually adhesive; with posterior adhesive region, usually circular but occasionally crescentic or divided into two or more smaller regions, often pedunculate; some with lamellated rhabdites, if present restricted to anterior region of body; duogland adhesive system absent; locomotory cilia usually absent; outer body layer divided into a series of syncytial epidermal plates; statocyst absent; paired ocelli usually present; mouth terminal or ventral; pharynx tubular or bulbous, usually oriented anteriorly, sometimes reduced; intestine in form of simple sac or with weak lateral diverticula; paired protonephridial system present, usually with two lateral excretory vesicles; with one to 10 pairs of testes; sperm biflagellated, flagella not incorporated into body of sperm, $9+'1'$ microtubule arrangement; male organ usually armed, usually with eversible cirrus mounted on tubular or conical shaft; ovary single; vitellarium lateral or scattered in form of large follicles over intestine; eggs ectolecithal.

Habitat: Entirely freshwater; ectocommensal, primarily on external body surfaces, gills, or lining of branchial chambers of decapod crustaceans, occasionally found on amphipods, molluscs, turtles, and hemipterans.

''Typhloplanoida''

See Figure 12 (**Plate 1**). Very small; anterior usually modified with prominent rhabdoid tracts or rarely with an impermanent sheathed proboscis, or with a permanent terminal invagination with proboscis glands; dermal and adenal rhabdites usually present; duogland adhesive system present; cilia uniform throughout all surfaces of body or restricted to ventral surface; brain undivided; statocyst absent; paired ocelli present or absent; tubular spinous, buccal region occasionally present; mouth usually midventral or posterior, occasionally anterior; pharynx usually ventrally oriented, plicate or bulbous; intestine in form of simple elongate sac; paired protonephridial system present; testes single or paired; sperm biflagellated, flagella not incorporated into body of sperm, 9 + '1' microtubule arrangement; single or paired seminal vesicles sometimes present; male system often with funnel-shaped stylet; sheathed, unarmed cirrus present; penis papilla sometimes present; ovary and vitellarium usually separate; ovary single, paired, or unpaired; vitellarium paired or a column of serially arranged follicles; usually with bursa copulatrix and seminal receptacle; vagina usually absent; eggs ectolecithal; male and female pores separate or combined, male anterior to female; common orogenital pore present or absent. The group is likely not monophyletic.

Habitat: Species known from freshwater, terrestrial, and marine environments; mostly free-living; a few known from the body surfaces of polychaete annelids.

Prolecithophora

See Figure 13 (**Plate 1**). With or without ciliated groove around anterior of body; anterior adhesive disc usually absent (present in Hypotrichinidae); extensive epidermal spicules present or absent; cilia uniform throughout all surfaces of body or restricted to ventral surface; brain encapsulated or not; statocyst absent; one to three pairs of ocelli present or absent; mouth anterior, midventral or posterior; with simple, plicate or weakly bulbous pharynx; intestine in form of simple elongate sac, well defined (surrounded by tunic of connective tissue) in most; paired protonephridial system present; testes, one or two, compact or diffuse; sperm biflagellated, flagella not incorporated into body of sperm, mitochondria with elaborate outer cell membrane foldings; seminal vesicle in some; male copulatory stylet rarely present; ovary and vitellarium not fully separated in some, but separated in others; ovary compact or diffuse, paired or not; vitellarium usually diffuse; accessory female openings present or not; eggs ectolecithal; male pore opening anterior to female opening but into common atrium; combined mouth and gonopore or gonopore opening separate from mouth.

Habitat: Predominantly marine, some inhabiting freshwater; free-living, or symbiotic (commensal or parasitic) on gills, on body surfaces, in mantle cavity of gastropod and lamellibranch molluscs, or on surface of small crustaceans; rarely parasitic on anal and branchial regions of fish; some of these associations may be phoretic, with the worm using the host merely for transport.

Tricladida

See Figure 14 (**Plate 1**). Usually large, flattened, elongate; body sometimes pigmented, terrestrial forms often colorful; some with triangular, semilunate, or pointed anterior region of body; caudal adhesive disc present or absent; lamellated rhabdites present in some; duogland adhesive system present; cilia uniform throughout all surfaces of body or restricted to ventral surface; statocyst absent; with many ocelli or one pair of ocelli (cave dwelling species lack ocelli), ocelli sometimes with distinct lens; mouth in middle or posterior half of body; pharynx plicate or tubular, posteriorly directed, usually one, occasionally more pharynges; intestine tripartite with one anterior and two posterior branches, posterior branches fused or not, diverticula sometimes present; anterior branch sometimes anterior to brain; protonephridial system paired; testes, two or many; sperm biflagellated, flagella not incorporated into body of sperm, 9 + '1' microtubule arrangement; seminal vesicle present or absent; male copulatory structures complex; penis usually pyriform, usually unarmed, but sometimes armed with spines or stylet; prostate organ usually absent; one pair of small ovaries usually at anterior of body, often anterior to brain; female copulatory structures variable, with or without copulatory bursa; accessory genital organs may be present in form of extra bursae each with separate pore; vitellarium follicular, extensive; genitointestinal canal sometimes present; eggs ectolecithal; gonopore usually single, rarely two or three; unique temporary embryonic pharynx (i.e., "blastomerenanarchie") and intestine replaced by definitive pharynx during development to adult stage.

Habitat: Predominantly free-living in marine, brackish water, freshwater, or moist terrestrial environments (suborders associated with habitats); one family known only from freshwater caves; some symbiotic with other invertebrates, for example, in mantle cavity of gastropods, or gill lamellae of horseshoe crabs, or on dorsal surface of skates.

Fecampiida

See Figure 15 (**Plate 1**). Evenly ciliated (dorsally and ventrally), with rhabdites (without ciliated groove); pharynx variabilis, or lacking; oral–genital pore terminal (or mouth, pharynx, and intestine lacking, or with pad of epidermal cells on dorsal side of body); ovaries and vitellaria separated; ovary and testes separated or combined in ovotestis; gonopore posterior or absent; thickening of cutaneous muscles.

Habitat: Symbiotic with invertebrates such as molluscs, crustaceans, polychaetes, and occasionally teleosts.

Subphylum Neodermata

Ehlers championed the recognition of the remaining platyhelminth groups as the Neodermata because they share a unique outer body covering in the form of a neodermis, which is sometimes also referred to as a tegument (**Figure 16**). Neodermatans generally begin life with a single-layered, cellular, ciliated epidermis, like most of the non-neodermatan platyhelminth groups. But, as they mature this outer epidermal layer is shed and replaced with a neodermis. This

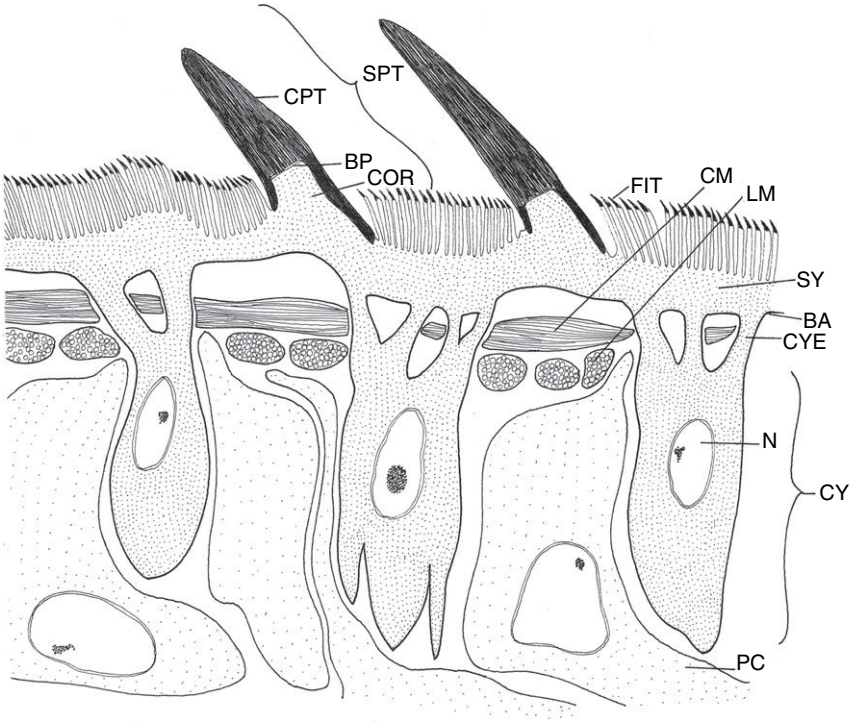

Figure 16 Neodermis of a cestode. Abbreviations: BA, basal lamina; BP, base plate; CM, circular muscle; COR, core; CPT, cap tubules; CYE, cytoplasmic extension; FIT, filithrix; LM, longitudinal muscle; SPT, spinithrix; SY, syncytium.

transformation usually occurs when the first larval stage encounters its host. The neodermis is characterized by the fact that the cytoplasm of neodermal cells is continuous throughout the surface of the animal as there are no cell membranes separating adjacent cells in this layer (i.e., it is a syncytial layer). Furthermore, the nuclei of these cells are generally located below the basal lamina and outer muscle layers of the body, in structures called cytons or pericarya. These are the nuclei of the stem cells, the cytoplasm of which grew outward to form the syncytial layer of the neodermis. The cytons are connected to the outer syncytial layer by thin cytoplasmic extensions. Furthermore, the configuration of the sperm flagella is unusual in neodermatans in that rather than remaining separate from the main sperm body, they are incorporated into the cytoplasm of the sperm body. Unlike other platyhelminths, the neodermatans are generally associated with one or more vertebrate hosts at some point in their lives.

There are four major neodermatan groups: the Monogenea (i.e., the Monopisthocotylea and Polyopisthocotylea), the Aspidogastrea and the Digenea (collectively referred to as the Trematoda), and the Cestoda. The orders of these major groups, or superfamilies in the case of the digeneans, are treated separately below.

Class Monogenea

Adult Monogenea (or Monogenoidea) are primarily external parasites of cold-blooded aquatic, or occasionally terrestrial, vertebrates. However, a few occur internally in the body cavity or very rarely the digestive system of their hosts and one parasitizes the eyes of hippopotamuses. The majority of monogeneans possess a ciliated, free-swimming larval stage known as an oncomiracidium, although the larvae of several groups are unciliated.

Adults generally possess both anterior and posterior attachment structures. The form of the anterior attachment structure varies among groups, consisting of one or two sucker-like organs, pseudosuckers, or grooves. In some cases this region is equipped with gland cells. In the past this anterior structure has been referred to as a prohaptor. The posterior attachment structure also varies widely in morphology among taxa and its form is the primary distinction between the two subclasses of monogeneans, the monopisthocotyleans and the polyopisthocotyleans. This structure is generally now referred to as a haptor, although in the past the term opisthaptor has also been used. This structure is also present in the oncomiracidial stage. The haptor may be symmetrical or asymmetrical, may bear glands, suckers, and may be subdivided into numerous loculi. In addition, the haptor of most monogeneans is armed with a series of hardened structures greatly facilitating attachment to the host. The terminology of these structures is based to some extent on their morphology, but also to a large extent on when they appear in the course of development. For example, the small hooked structures that are usually found around the periphery of the haptor of the ciliated larval stage, or oncomiracidium, and which persist into the adult stage of some monopisthocotyleans, are termed hooklets or uncinuli. The larger, more centrally located hooked structures are generally termed hamuli or anchors, depending on whether or not they are present in the

oncomiracidium. The more complex structures consisting of multiple sclerites, which are found only in polyopisthocotyleans, are termed clamps. Four rhabdomeric ocelli are present in at least one stage of development. The mouth is almost always located in the anterior region of the body. Most monogeneans possess a conspicuous muscular pharynx and an intestine that is usually divided into two, or rarely one, blind cecum; the caeca are occasionally branched or anastomose posteriorly. All monogeneans are hermaphroditic. The male and female genital pores are ventral and usually combined. The number of testes ranges from one to many among different groups. Most groups possess a single ovary that varies somewhat in form from compact to double inverted U-shaped. The male intromittent organ can be a penis or a cirrus, but the exact form of this feature is not well known in some groups. The terminal genitalia are often complex. The excretory system consists of two sets of protonephridia that open separately to the outside, usually in the anterior of the body, but that may be connected at some point in the body.

Molecular work has called the monophyly of the class Monogenea into question. This is reflected in the unresolved nature of this node in the tree presented in **Figure 1**. However, the mutual monophyly of the subclasses Monopisthocotylea and Polyopisthocotylea appears to be well supported. Members of these subclasses are relatively easy to recognize. Most conspicuously, the Polyopisthocotylea possess a haptor that is subdivided into multiple suckers or bears distinctive attachment structures known as clamps, and the Monopisthocotylea, possess a haptor that, although it may bear loculi, is undivided and, although it may bear anchors or hamuli, never bears clamps. Furthermore, unlike the monopisthocotyleans, the polyopisthocotyleans possess a genitointestinal canal such that their genital ducts open into their intestine. Boeger and Kritsky (2001) provide a number of additional features unique to each subclass. The interrelationships among the orders in each subclass are controversial. The orders in each Subclass are treated below in alphabetical.

To make the following diagnoses more concise, unless mentioned, it should be assumed that an order possesses the following: a posterior, discoidal, undivided, symmetrical haptor, a conspicuous muscular pharynx, a gut consisting of two blind intestinal ceca, paired testes, biflagellated sperm, flagella incorporated into body of sperm, 9+'1' microtubule arrangement, a single ovary, a vitellarium that is follicular with follicles arranged in two extensive lateral fields, operculate ectolecithal eggs, and a single, ventral genital pore (**Plate 2**).

Subclass Monopisthocotylea

Capsalidea

See Figure 17 (**Plate 2**). Anterior end with paired petaloid head organs or paired glandular pseudosuckers; haptor sometimes subdivided by septa into central area and multiple peripheral loculi, with 14 marginal hooklets and two or four central anchors and two anterior sclerites; mouth ventral; intestinal ceca fused posteriorly, with lateral and axial diverticula; testes, two to many; sperm microtubules absent; vas deferens forming bipartite external seminal vesicle and simple internal vesicle, or seminal vesicle absent; penis sac present or absent; penis present or absent; penis elongate, muscular, spines absent; some with cirrus; prostatic complex present; vagina present or absent; seminal receptacle present or absent; genital apertures usually combined, marginal; oviparous.

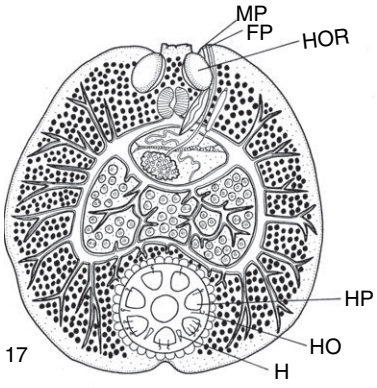
Habitat: Adults parasitic on skin or gills of marine teleosts (including remoras), or on skin or gills of elasmobranchs.

Dactylogyridea

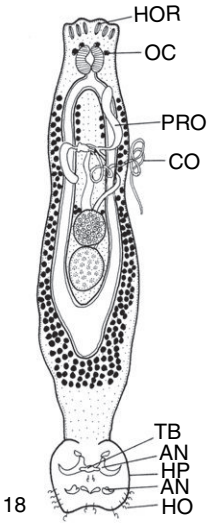
See Figure 18 (**Plate 2**). With two or more pairs of head organs, with or without cephalic glands; posterior half of body covered with anteriorly directed cuticular spines or not; haptor with one or two pairs of anchors supported by one to four transverse bars, with or without accessory plaques, occasionally with two suckers and median terminal anchor complex, usually 14 or 16 marginal hooklets; mouth subterminal, ceca fused posteriorly or not, with lateral diverticula or not; testes usually one; sperm with one axoneme; vas deferens encircling left cecum; seminal vesicle usually present; prostatic complex present; male copulatory organ sclerotized, elongated, muscular, ovary compact, lobed or tubular; vitellarium follicular or occasionally divided into tubular lobules in form of frond-like sprays spreading in two or three lateral groups (Protogyrodactylidae), coextensive with intestinal ceca; seminal receptacle and vagina present or absent; oviparous; eggs oval or tetrahedral; genital aperture median or marginal.

Habitat: Adults parasitic on gills and skin of marine and freshwater, occasionally brackish water, teleosts; rarely on gills or in heart of elasmobranchs.

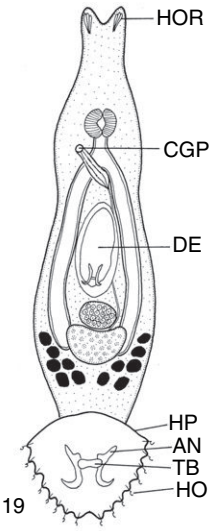
Gyrodactylidea



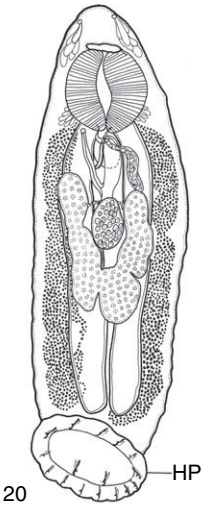
See Figure 19 (**Plate 2**). With two head organs; haptor usually with one pair of anchors often supported by dorsal and ventral transverse bars with 16 marginal hooklets; mouth ventral, intestinal ceca, one or two, usually not fused posteriorly; testis single; sperm microtubules absent; vas deferens encircling left caecum; male copulatory organ sclerotized or muscular, spines present or absent; accessory piece present; vitellarium symmetrical, near posterior part of intestinal cecae; vagina absent or present, opening ventrally near left margin of body; genital pore marginal; most species viviparous; eggs oval or tetrahedral.



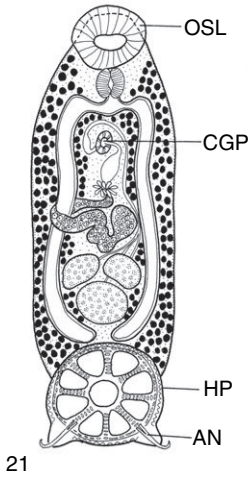
Habitat: Adults parasitic on gills or skin of freshwater and marine teleosts, in stomach and intestine of amphibians, and gills and tentacles of squid; udonellids on marine crustaceans.



Lagarocotylidea



See Figure 20 (**Plate 2**). Oral sucker-like organ absent; with cephalic glands; haptor with 14 submarginal and 2 subcentral hooklets; mouth midventral; ceca not fused posteriorly, without lateral diverticula; with single U- or V-shaped testis; vas deferens encircling left caecum; seminal vesicle present; prostatic reservoir dorsal to copulatory complex; male copulatory organ sclerotized, with accessory piece; ovary compact; vitellarium consisting of two dense bilateral bands of follicles; seminal receptacle absent; vaginal pore dextro-ventral at level of genital pore; eggs without filaments; genital aperture median.



Habitat: Adults parasitic in the cloaca of salamanders.

Monocotylidea

See Figure 21 (Plate 2). With single anterior sucker or several sucker-like depressions or paired head organs (lobes) with cephalic glands; haptor aseptate or divided by septa into loculi, often with one pair of anchors, with or without marginal papillae, usually with 14 marginal hooklets; ocelli present or absent; mouth ventral, intestinal ceca occasionally fused posteriorly, occasionally with lateral diverticula; with one to several testes; sperm microtubules lying along one quarter of cell periphery, with two axonemes one of which is reduced; male copulatory organ usually sclerotized; ovary tubular, usually encircling right intestinal caecum; ventral vaginal pore sometimes present; genital pore usually median.

Habitat: Adults parasitic on skin, gills, and sometimes nasal bulbs of elasmobranchs; occasionally in coelom, oviducts, and cloaca of elasmobranchs; occasionally in cloaca of holocephalans.

Montchadskyellidea

See Figure 22 (Plate 2). Haptor with one pair of anchors lacking supporting bars, with 14 marginal hooklets; mouth subterminal, gut diverticula present; testis single; male copulatory organ sclerotized; vas deferens encircling left caecum; accessory piece present; ovary encircling right caecum; one midventral vagina present; genital pores separate, opening on separate ventral papillae.

Habitat: Adults parasitic in gut of marine teleosts.

Subclass Polyopisthocotylea

Chimaericolidea

See Figure 23 (Plate 2). Single, weak oral sucker-like organ usually present; body with highly contractile, sometimes with very long, posterior peduncle; haptor with four pairs or four alternating rows of two short-stalked symmetrical clamps, and terminal lappet-bearing hooks; ceca with lateral diverticula, extending posteriorly into haptor; with numerous testes; seminal vesicle present or absent; cirrus muscular, armed or not; prostatic complex present or absent; ovary lobed or branched; with two lateral vaginae opening into vitelline duct; seminal receptacle present or absent; uterus with numerous longitudinal loops, with or without lateral branches.

Habitat: Adults parasitic on gills or in gill chamber of holocephalans.

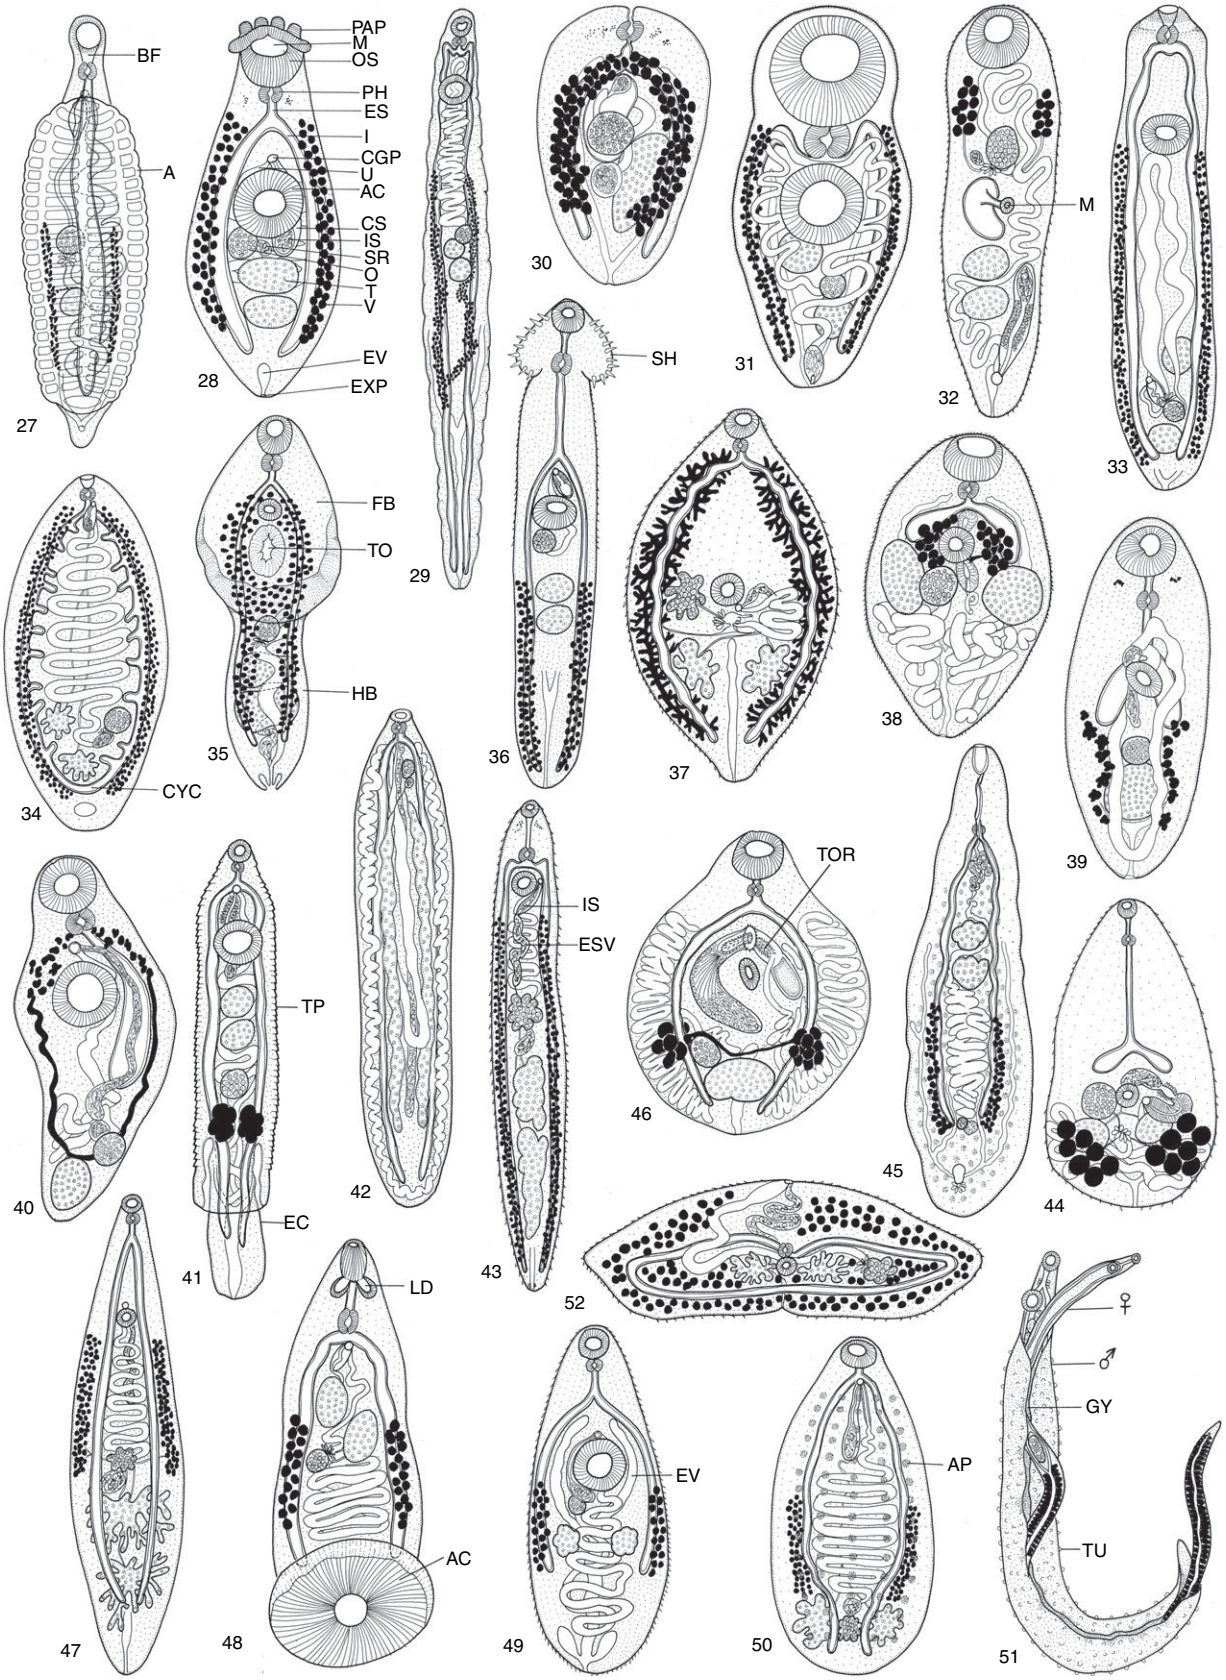
Diclybothriidea

See Figure 24 (Plate 2). With anterior muscular, paired ventral "bothria" or oral sucker-like organ; haptor with three pairs of sessile suckers, with medial, haptoral appendix bearing three pairs of hook-like sclerites or one pair of terminal suckers and two small anchors; each haptoral sucker with single, large, curved, hooked sclerite; mouth terminal or nearly so; ceca united posteriorly, with lateral diverticula; testes numerous; male intromittent organ usually armed; ovary tubular, convoluted; with two lateral vaginae; uterus preovarian; vitellarium sometimes extending posteriorly into haptor; eggs with or without polar filaments, occasionally forming chains.

Habitat: Adults parasitic on gills of sturgeon, paddlefish (chondrosteans), and elasmobranchs.

Mazocraeidea

See Figure 25 (Plate 2). With two anterior buccal suckers, occasionally enlarged in form of discoid adhesive organ with conical papillae; haptor symmetrical or asymmetrical, set off from body by distinct peduncle or not, distinctly bilobed or not, usually with four to numerous pairs of clamps, without marginal hooklets, terminal lappet usually present; terminal lappet with one to three pairs of similar or dissimilar hook-like sclerites, bifid or not; testes numerous; copulatory apparatus consisting of sheaf of long spines or longitudinally striated sheath; male intromittent organ present or absent, armed or unarmed; ovary tubular, winding, convoluted, rarely compact or inverted U-shaped; vitellarium sometimes extending posteriorly into haptor; seminal receptacle present or absent; vagina present or absent, paired or not; vaginal aperture spined or not, conical sclerite in front of vaginal pore or not; eggs with two filaments; genitointestinal canal present; genital pores common or separate, genital pore sometimes sucker-like; in rare cases (Diplozoidae) two adults permanently fused in form of an X.



Habitat: Adults parasitic on gills or occasionally mouth cavity of marine, or sometimes freshwater teleosts; sometimes on crustaceans in mouth cavity of teleosts.

Polystomatidea

See Figure 26 (Plate 2). With anterior muscular oral sucker-like organ; haptor with three but occasionally one pair of suckers, usually with one to two pairs of hamuli, sometimes with accessory spines or spurs, often with marginal hooklets, sometimes with medial appendix-like prolongation; ocelli usually absent; mouth terminal or subterminal; ceca occasionally fused posteriorly, often with lateral diverticula; testes, one to many; seminal vesicle present; male intromittent organ usually armed with hooks or spines; genitointestinal canal present; ovary compact; vitellarium rarely compact; uterus anterior or opposite ovary or reaching posterior of body; with two lateral vaginae.

Habitat: Adults parasitic in mouth, pharynx, esophagus, urinary bladder of frogs and toads and gills of tadpoles; mouth, esophagus, nasal passages, or urinary bladder of

turtles; mouth and gills of Australian lungfish; urinary bladder of urodeles; eyes of hippopotamuses.

Class Trematoda

Subclass Aspidogastrea

See Figure 27 (**Plate 3**). With ventral holdfast organ in form of linear series of 20–100 suckers, numerous transverse rugae, or extensive adhesive disc subdivided by septa into numerous loculi; disc with or without papillae; neodermis with microvilli in form of hemispherical microtubercles; buccal funnel at anterior end of body; oral sucker usually absent; oral lobes occasionally present; with one or two blind intestinal ceca; excretory vesicle present, V-shaped, excretory pore near posterior of body; with one, two, or many testes; sperm biflagellated, flagella incorporated into body of sperm, 9 + '1' microtubule arrangement; cirrus present; cirrus-sac present or absent; ovary single; vitellarium follicular or tubular, if follicular usually with multiple lateral follicles, rarely single median tube flanked by follicles, if tubular, two tubes; uterus generally long; Laurer's canal present or absent; Mehlis' gland present; eggs ectolecithal; single common genital pore.

Habitat: Adults endoparasites in kidneys, pericardial chamber, gill lamellae, or intestine of freshwater and occasionally marine lamellibranch molluscs, kidneys (renal cavities) and pericardial chamber of marine and freshwater gastropod molluscs, occasionally guts of turtles or freshwater and marine teleosts, gall bladder and bile ducts of elasmobranchs, or in lumen of rectal glands of Holocephali.

Subclass Digenea

Almost all digeneans are endoparasites as adults in various organ systems of vertebrates. They are monophyletic and are most easily characterized by their possession of a unique series of developmental stages that include miracidium, sporocyst, redia, cercaria, and metacercaria. Variation in life cycles seen among digenean species suggests that perhaps only a subset of these ontogenetic stages should be considered to distinguish the subclass. Most adult digeneans possess an anterior sucker (or oral sucker), which is usually (Figure 28, **Plate 3**), but not always (Figure 32, **Plate 3**), associated with the mouth. Most also possess a second sucker (or acetabulum) that is usually midventral (Figure 49, **Plate 3**), but occasionally posterior in position (Figure 48, **Plate 3**). The body of some species is divided into two parts (Figure 35, **Plate 3**). Other major variations in adult body form include a posterior telescoping ecsoma (Figure 41, **Plate 3**), a sucker-like ventral adhesive tribocytic organ (Figure 35, **Plate 3**), one or more anterior collars of large spines (Figure 36, **Plate 3**), and paired anterior retractile proboscides. Most species possess an anterior mouth that opens into a bulbous pharynx and an intestine consisting of two or occasionally one blind cecum, with or without diverticula. However, the ceca in some species are connected to one another posteriorly (Figure 34, **Plate 3**) or open into the excretory bladder. The excretory system generally consists of two sets of protonephridia, both of which empty into a common excretory vesicle. This vesicle is variable in shape among taxa and usually opens at the posterior end of the body. With the exception of the schistosomes (Figure 51, **Plate 3**) and some didymozoids, all digeneans are hermaphroditic. The male intromittent organ is usually a cirrus, which may or may not be armed with spines, and may or may not be surrounded by a cirrus-sac. Testes are usually oval, but occasionally lobed or tubular; testes can be single, paired, or numerous. Sperm may be stored inside or outside the cirrus-sac in an internal or external seminal vesicle respectively; some taxa possess both vesicles. Most digeneans possess a single ovary that may be round, lobed, or tubular in form. Digeneans lack a vagina; instead, sperm enters the female system through the uterus, which opens, generally in combination with the male system, into a common genital pore. Some species possess a seminal receptacle in the form of a basal expansion of the uterus or as diverticula of the Laurer's canal. A Laurer's canal, which may or may not open to the outside, may be present or absent. The function of the Laurer's canal is unknown, but it is considered by some to represent the remnant of a vagina. The vitellarium consists of columns of numerous follicles along both sides of the body in most taxa, but is occasionally present as one or a pair of compact follicles or vitelline chords.

With at least 1592 nominal genera, the digeneans are by far the most diverse of the platyhelminth groups. Unlike all of the other major platyhelminth groups, superfamily, rather than order, is the highest taxonomic category of relative stability within the subclass. Unfortunately, although the phylogenetic relationships among some of the major digenean taxa have been explored (e.g., Cribb *et al.*, 2001; Olson *et al.*, 2003), the

Transversotrematoidea: adult of *Transversotrema* sp. Abbreviations: A, adhesive disc; AC, acetabulum; AP, adhesive papillae; BF, buccal funnel; CGP, common genital pore; CS, cirrus-sac; CYC, cyclocoel; EC, ecsoma; ES, esophagus; ESV, external seminal vesicle; EV, excretory vesicle; EXP, excretory pore; FB, forebody; GY, gynecophoral canal; HB, hindbody; I, intestine; IS, internal seminal vesicle; LD, lateral diverticula of oral sucker; M, mouth; O, ovary; OS, oral sucker; PAP, papilla; PH, pharynx; SH, spiny head collar; SR, seminal receptacle; T, testis; TO, tribocytic organ; TOR, terminal organ; TP, transverse plications; TU, tubercles; U, uterus; V, vitellarium.

relationships among the 25 superfamilies and 148 families remain controversial and poorly understood. The digeneans are treated here following the classification scheme embraced in the recent CABI keys (see Gibson *et al*., 2002; Jones *et al*., 2005; Bray *et al*., 2008); superfamilies are considered below in alphabetical order. It is important to note, however, that the monophyly of many of these superfamilies also remains uncertain.

To make the following diagnoses more concise, unless mentioned, it should be assumed that a superfamily possesses the following features: no specialized body regions or structures, both suckers (oral sucker and acetabulum) are present, the mouth opens into the oral sucker, a muscular pharynx is present, the gut consists of two blind intestinal ceca, they are hermaphroditic, the testes are compact and paired, the sperm are biflagellated and the flagella are incorporated into the body of the sperm, the flagella of the sperm possess a 9 + '1' arrangement of microtubules, a cirrus and cirrus-sac are present, the ovary is single, the vitellarium is follicular and the follicles are arranged in two lateral fields, there is a common genital pore, the eggs are ectolecithal and the epidermal cells of the miracidium are covered with cilia.

Allocreadioidea

See Figure 28 (**Plate 3**). Oral sucker with or without one or three pairs of muscular papillae; body surfaces usually unspined; genital pore opens near acetabulum; excretory vesicle I-shaped. Developmental stages: Cotylocercous xiphidiocercaria, ophthalmoxiphidiocercaria, trichocercous, or homalometrine cercaria; metacercaria usually encysts in invertebrate hosts, rarely on substrate.

Habitat: Adults parasitic in digestive tract and occasionally gall bladder of marine and freshwater teleosts, or occasionally gall bladder of freshwater turtles, or intestine of chameleons; some species progenetic in insects.

Azygioidea

See Figure 29 (**Plate 3**). Body surface usually unspined; genital pore opens anterior to acetabulum; sinus organ present; uterus usually entirely preovarian; excretory vesicle Y-shaped. Developmental stages: Cercaria nonoculate furcocercous, furcocystocercous, or cystocercous; metacercaria unknown.

Habitat: Adults parasitic in stomach or body cavity of elasmobranchs (sharks and rays) and in stomach of freshwater teleosts and holosteans (gar, bowfin, etc.).

Bivesiculoidea

See Figure 30 (**Plate 3**). Oral sucker and acetabulum absent; body surface with minute spines; testis single; gential pore midventral; uterine seminal recepticle present; excretory vesicle V-shaped. Developmental stages: Cercaria furcocercous, cystophorous, oculate furcocystocercous.

Habitat: Adults parasitic in intestine of marine and occasionally freshwater teleosts.

Brachylaimoidea

See Figure 31 (**Plate 3**). Body surfaces spined or not; ovary usually between testes; ovary and testes often close to posterior extremity of body; genital pore opens in hindbody, often near posterior extremity; excretory vesicle Y-shaped. Developmental stages: Cercaria furcocercous or cercariaeum with rudeimentary or no tail that may or may not leave the sporocyst; metacercaria encysted or unencysted in second intermediate host or within sporocyst in second intermediate host.

Habitat: Adults parasitic in intestine of aquatic birds and terrestrial mammals, birds and occasionally reptiles and amphibians.

Bucephaloidea

See Figure 32 (**Plate 3**). Body surface usually spined; oral sucker and acetabulum absent; anterior holdfast organ a rhynchus, with or without sucker; mouth opening on ventral surface; intestinal caecum simple, not bifurcating; genital pore usually terminal; excretory vesicle I-shaped. Developmental stages: Cercaria of bucephalid type; metacercaria encyst in teleosts.

***Habitat*:** Adults parasitic in digestive system or sometimes in swim bladder or body cavity of marine and freshwater teleosts and occasionally intestine of salamanders.

Clinostomoidea

See Figure 33 (**Plate 3**). Oral sucker weak, enveloped in collar-like anterior end of body, pharynx rudimentary or small; genital pore opens in posterior third of body. Developmental stages: Brevifurcate cercaria; metacercaria encysts on vertebrate hosts.

Habitat: Adults parasitic in mouth and esophagus of alligators and piscivorous birds.

Cyclocoeloidea

See Figure 34 (**Plate 3**). Oral sucker usually absent, occasionally present; acetabulum absent or, if present, weakly developed; intestinal ceca usually fused posteriorly to form cyclocoel; genital pore opens near pharynx. Developmental stages: Cercaria usually tailless or with rudimentary tail; metacercaria encysts within sporocyst or redia in molluscan host.

Habitat: Adults parasitic in nasal sinuses, nasolacrimal sinus, infraorbital sinuses, respiratory tract, and occasionally coelom or intestine of birds.

Diplostomoidea

See Figure 35 (**Plate 3**). Body generally divided into anterior forebody and posterior hindbody; tribocytic organ present posterior to acetabulum; reproductive organs generally concentrated in hindbody; genital pore usually opens in posterior of body. Developmental stages: Cercaria variable; metacercaria generally encysts on vertebrate hosts, very rarely invertebrate hosts.

Habitat: Adults parasitic in digestive system of birds and reptiles, especially crocodilians and snakes, sometimes amphibians, sometimes mammals including dogs, cats, dolphins, and some monotremes.

Echinostomatoidea

See Figure 36 (**Plate 3**). Spiny head collar often present; two anterior, retractile, spiny proboscides rarely present; body usually spined; ceca sometimes with lateral diverticula; hermaphroditic-sac sometimes present, often with cirrus-sac, cirrus occasionally absent; genital pore variable in position. Developmental stages: Cercaria echinostome-like,

megalurous, gymnocephalous megaperid or haplosplanchnid; metacercaria usually encysts on aquatic vegetation, sometimes on vertebrates, rarely in invertebrates.

Habitat: Adults parasitic in the intestinal tract, gall bladder, bile duct, liver, lungs, nasal cavity, conjunctival sac, bursa fabricius, and orbit of vertebrates including a variety of marine and freshwater teleosts, birds, crocodiles, turtles, snakes, lizards, marine mammals including pinnepeds and cetaceans, and a variety of terrestrial herbivorous mammals.

Gorgoderoidea

See Figure 37 (**Plate 3**). Body surfaces spined or not; acetabulum well developed, sessile or protuberant; intestinal caeca usually two, occasionally one, may unite posteriorly; cirrus-sac present or absent; genital pore usually anterior to acetabulum; vitellarium follicular or dendritic, usually limited in extent; uterus usually in hindbody; excretory vesicle variable. Larvae: Microcercous xiphidiocercaria; metacercaria encysts on invertebrates or vertebrates.

Habitat: Adults parasitic in intestine, gall bladder, bileducts, pancreatic ducts, body and pericardial cavities, urinary bladder, ureters, swim bladder, nasal and paranasal sinues, lungs, brain, or encysted in skin and in wall of digestive tract of a diversity of vertebrates (elasmobranchs, teleosts, herptiles, birds, and mammals).

Gymnophalloidea

See Figure 38 (**Plate 3**). Mouth opening into oral sucker or acetabulum (bucephalids); cirrus-sac present or absent; cirrus sometimes absent; genital pore variable in position. Developmental stages: Cercaria often produced in branched sporocysts; cercaria often with rudimentary tail or tailless, often gasterostomous; metacercaria encysts on vertebrate hosts or within sporocyst in molluscan host; very rarely encysts in invertebrates.

Habitat: Adults parasitic in liver, bile duct, gall bladder, digestive tract of freshwater and marine teleosts, or large intestine, cloaca, bursa fabricius of birds, occasionally mammals (such as, for example, hedgehogs, rabbits, ruminants).

Haploporoidea

See Figure 39 (**Plate 3**). Body surfaces usually spined; eye-spot pigment usually present, dispersed in forebody; oral sucker with or without lobes or hood; testes usually one, occasionally two; cirrus-sac absent; genital pore anterior to acetabulum; excretory vesicle I-, Y-, or V-shaped.

Habitat: Adults parasitic in digestive system of marine, freshwater, and estuarine teleosts.

Haplosplanchoidea

See Figure 40 (**Plate 3**). Body surfaces unspined; oral sucker normal, occasionally replaced by disc with or without lobes; intestinal caecum single; testis usually one, rarely two; cirrus-sac usually absent, rarely present; genital pore anterior to acetabulum; excretory vesicle Y-shaped.

Habitat: Adults parasitic in digestive system of marine, freshwater, and estuarine teleosts.

Hemiuroidea

See Figure 41 (**Plate 3**). Body generally elongate; sometimes with posterior telescoping ecsoma; body surface unspined but often with transverse plications; ceca sometimes fused to one another posteriorly, or fused posteriorly with excretory vesicle; usually hermaphroditic but one group (didymozoids) occasionally gonochoristic (if gonochoristic adult sexually dimorphic, male and female usually encysted in pairs); hermaphroditic duct almost always present; cirrus-sac often absent; vitellarium often in form of rosette or tubular, or in two compact masses. Developmental stages: Miracidium spinous, lacking cilia; cercaria cystophorous; metacercaria usually unencysted in invertebrate or vertebrate hosts, occasionally within redia in molluscan host.

Habitat: Adults parasitic in digestive tract or swim bladder of freshwater and marine teleosts and rarely elasmobranchs; some associated with branchial cavities of marine teleosts and elasmobranchs; occasionally in mouth of frogs or stomach of sea snakes.

Heronimoidea

See Figure 42 (**Plate 3**). Body surfaces unspined; oral sucker often poorly developed; acetabulum absent; genital pore at level of pharynx; testes elongate, tubular, extend for length of body; vitellarium in form of slender elongate bands, extend for much of length of body; excretory vesicle tubular. Developmental stages: cercaria amphistomate; metacercaria apparently lacking, infection of definitive host is through ingestion of cercaria in the molluscan host.

Habitat: Adults parastic in lungs and trachea of freshwater turtles.

Lepocreadioidea

See Figure 43 (**Plate 3**). Body surfaces spined or not; with or without circumoral spines; oral sucker occasionally with papilliform extensions; acetabulum ventral or rarely at posterior end of body; ceca open into excretory vesicle or not; one or usually two intestinal ceca present; with two to many testes; cirrus-sac usually present, sometimes absent; hermaphroditic duct in some; external seminal vesicle in some; internal seminal vesicle bipartite in some. Developmental stages: Gymnophalous cercaria, produced in redia; metacercaria encysts on invertebrates, or on substrate, rarely in sporocyst or redia in molluscan host.

Habitat: Adults parasitic almost exclusively in digestive tract, rarely gall bladder or urinary bladder of marine teleosts; one record from lungs of reptile.

Microphalloidea

See Figure 44 (**Plate 3**). Body surfaces spined or not; oral sucker may be surrounded by semicircular collar of spines; acetabulum poorly developed, rarely absent; gut usually present, occasionally lacking or poorly developed (with short ceca); cirrus-sac present or absent; genital atrium sometimes with complicated accessory organs; vitellarium usually in restricted symmetrical clusters of large follicles; excretory system V-, Y-, or I-shaped. Developmental stages: Xiphiodiocercaria of ubiquita, microphallous, or virgulate type; metacercaria encysts on invertebrates or vertebrates, or occasionally in sporocyst in the molluscan host.

Habitat: Adults parasitic in many organ systems of most vertebrate classes.

Microscaphidioidea

See Figure 45 (Plate 3). Body surfaces spined or not; oral sucker and acetabulum absent; part of all of ventral surface may function as accessory attachment organ; some with ventral papillae; pharynx with or without paired intra or extramural sacs; cirrus-sac absent; uterine seminal receptacle often present; excretory system entirely or partly reticular. Developmental stages: cercaria apharyngeal monostomous; metacercaria encysting on vegetation.

Habitat: Adults parasitic in digestive system of marine and freshwater teleosts, and turtles.

Monorchioidea

See Figure 46 (Plate 3). Body surfaces usually spined; oral sucker rarely with ring of spines; testes one, two, or rarely 8; uterus usually with numerous coils; terminal organ associated with terminal part of uterus in some; excretory vesicle I-, V-, or Y-shaped. Developmental stages: cercaria often microcercous or completely lacking tail, some with stylet; metacercaria often progenetic (i.e., producing eggs), encysting in molluscs, planarians, aquatic annelids and larval insects.

Habitat: Adults parasitic in digestive system of marine and freshwater teleosts.

Opisthorchiodea

See Figure 47 (Plate 3). Body sometimes spined; oral sucker sometimes with ring of spines; cirrus-sac usually lacking; hermaphroditic duct sometimes present opening into genital atrium; acetabulum sometimes enclosed in ventrogenital sac, with or without gonotyl; seminal vesicle when present often bipartite. Developmental stages: Cercaria generally with ocelli, pleurolophocercous, parapleurolophocercous or gymnocephalus cercaria; metacercaria encysts on vertebrates, rarely invertebrates.

Habitat: Adults parasitic in stomach, intestine, occasionally bile ducts of marine teleost fishes, snakes, lizards, birds, and mammals; occasionally ovary of freshwater teleosts; occasionally progenetic encysted in musculature of frogs.

Paramphistomoidea

See Figure 48 (Plate 3). Usually unspined; oral sucker often with paired lateral diverticula, occasionally one unpaired diverticulum; acetabulum posterior or subterminal, sometimes with muscular lip, occasionally lacking; body occasionally with caudal appendages; usually with lymphatic system (usually with one to three longitudinal trunks); genital sucker sometimes present; ventral pouch sometimes present; cirrus-sac present or absent; hermaphroditic-sac in some. Developmental stages: Cercaria lacking acetabulum or with posterior acetabulum, develops from redia or branched sporocyst; metacercaria usually encysts on vegetation, but occasionally on frogs, metacercarial stage occasionally lacking.

Habitat: Adults parasitic in digestive tract of marine and freshwater teleost fishes, snakes, marine turtles, amphibians, birds and a wide diversity of marine and terrestrial mammals (including humans), or in lungs and trachea of turtles and tortoises.

Plagiorchioidea

See Figure 49 (Plate 3). Body usually spined; oral sucker occasionally with pair of muscular lateral papillae; acetabulum rarely vestigial; fields of vitellarium usually restricted anteriorly and posteriorly; excretory vesicle Y-shaped. Developmental stages: Cercaria of leptocercous, microcercous, cystocercus, armatao, ornatae, virgulate, ubiquita, or corcacriaeum type; often developing in daughter sporocysts in gastropod or lamellibranch molluscs; metacercaria encysts in terrestrial arthropods or gastropods.

Habitat: Adults parasitic in digestive system of mammals (especially bats), turtles, amphibians, reptiles, and occasionally fishes; liver and bile ducts of mammals, birds, and reptiles; cloaca and oviducts of birds and mammals; bursa fabricius of birds; urinary bladder of fishes and amphibians; coelom or pericardial chamber of elasmobranchs; occasionally progenetic in leeches and crustaceans.

Pronocephaloidea

See Figure 50 (Plate 3). Body surfaces spined or unspined; acetabulum absent; often with ventral longitudinal ridge or series of ventral papillae; head collar present or absent; pharynx absent; male and female pores occasionally separate, pore(s) variable in position; uterus usually in form of transverse coils anterior to ovary; vitellarium follicular, rarely in form of single lobed mass; excretory vesicle V- or Y-shaped, sometimes extremely modified in structure; posterior invaginations of body forming secondary excretory vesicle or protrusible tentacles associated with excretory vesicle. Developmental stages: Cercaria monostomate, bi or trioculate, with posterior adhesive glands at posterior of body; metacercaria encysts on substrate or on invertebrate hosts, rarely in sporocyst or redia within molluscan host.

Habitat: Adults parasitic in oviduct, urinary and gallbladders, pancreas, liver, respiratory tract, tissues or digestive system of teleosts, marine turtles, marine iguanids, birds, mammals (including dugongs, cetaceans, bats, rodents, and insectivores), occasionally in bursa fabricius of birds.

Schistosomatoidea

See Figure 51 (Plate 3). Gonochoristic or hermaphroditic, if gonochoristic, male with ventral gynecophoral canal in which female resides for much of her life; surface of male body often with tubercles, with or without spines; pharynx usually lacking; both oral sucker and acetabulum present, or one or both lacking; ceca of gut often anastomosing at several points along length; one, two or many testes; genital pores separate or combined. Developmental stages: Cercaria apharynegeate, brevifurcate, sometimes also lophophorate; metacercarial stage lacking; cercaria develops into schistosomula; first host usually a mollusc but rarely an annelid.

Habitat: Adults parasitic in blood vessels or heart of freshwater and marine teleosts, elasmobranchs, holocephalans, usually freshwater (but sometimes marine) birds and mammals (including humans), crocodiles, and marine and freshwater turtles.

Transversotrematoidea

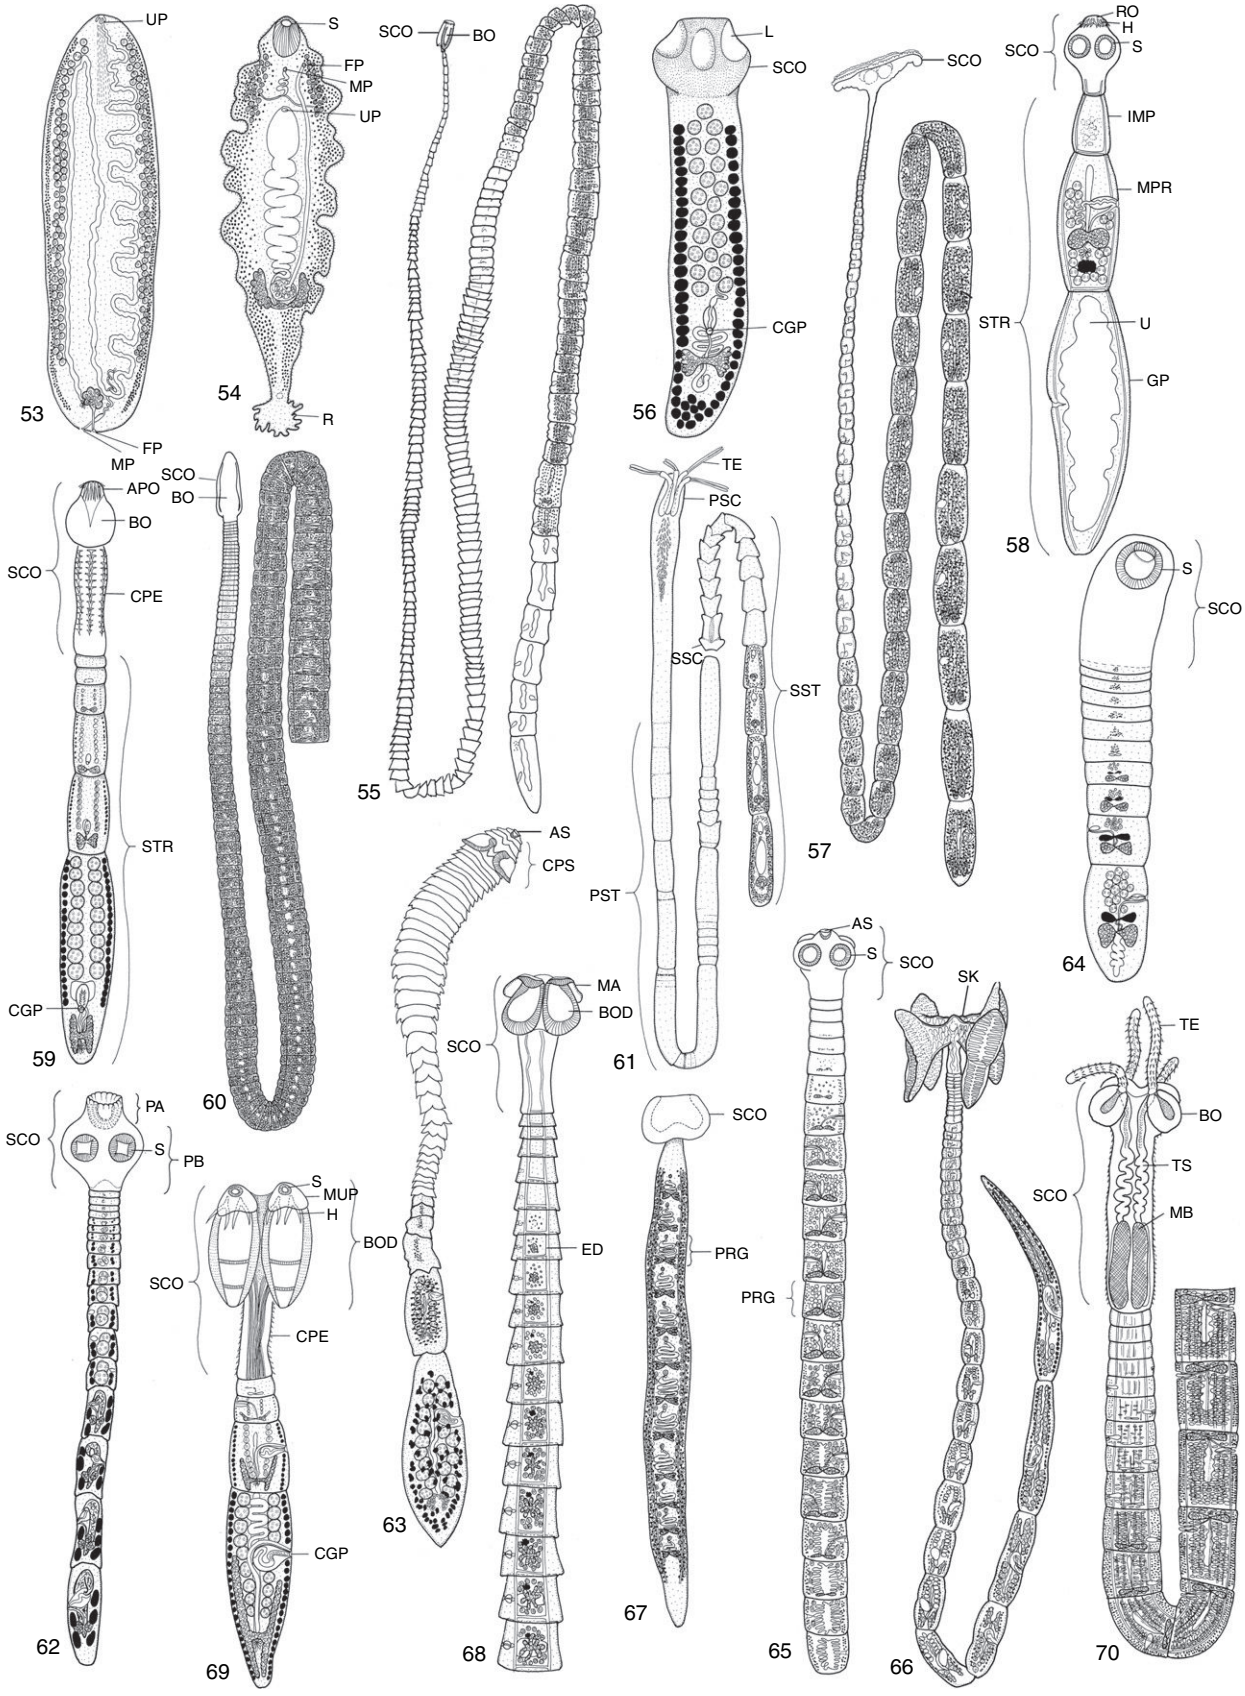
See Figure 52 (Plate 3). Body transversely elongated; spined; ceca united posteriorly to form transverse cyclocoel; excretory

vesicle curved to right, receiving collecting vessels from both sides of body; cirrus absent; genital pore anterior. Developmental stages: Cercaria brevifurcate with pair of anterior lateral appendages; metacercarial stage lacking; cercaria infects definitive host cutaneously and develops directly into adult stage.

Habitat: Adults parasitic under scales of freshwater, brackish water, and marine teleosts.

Class Cestoda

The cestodes, or tapeworms, conspicuously differ from almost all other platyhelminth groups in their lack of all elements of a digestive system, the only exceptions perhaps being the amphilinideans and gyrocotylideans, the anterior attachment organ of which is considered by some to represent a vestige of a digestive system. Thus, in general, the cestodes have no mouth, pharynx, esophagus, or intestine at any stage in their development. Rather, they absorb nutrients, in the form of very small molecules, directly through the outer layer of their body. There is evidence to suggest that their unique neodermal surface extensions, known as microtriches, assist in this process. Microtriches typically consist of an outer electron-dense cap composed of cap tubules, a baseplate, and a basal core consisting of an extension of the cytoplasm of the tegument (**Figure 16**). The entire structure is surrounded by a plasma membrane. These structures may also assist with attachment. Microtriches appear to be of two basic types. The larger form, termed a spinithrix (pl. spinitriches) (SPT in **Figure 16**), is greater than 200 nm in width; the smaller form, termed a filithrix (pl. filitriches) (FIT in **Figure 16**), is less than or equal to 200 nm in width.



The majority of tapeworms have a body consisting of an attachment region called the scolex, followed by a series of compartments, termed proglottids, that are collectively referred to as the strobila. Scolex morphology varies significantly among the various tapeworm orders. The scolex is simple in some groups, but it is more commonly equipped with attachment structures such as hooks, suckers, loculi, or hooked tentacles. In some groups, the scolex is subdivided into two or four flexible bothria or four muscular bothridia. Bothridia can be distinguished from bothria in their possession of discrete inner and outer membranes bounding their musculature, visible most readily in histological section.

The proglottids of most tapeworms are hermaphroditic, each containing one, or less commonly two or more, sets of male and female reproductive organs. A few orders of tapeworms (specifically the amphilinideans, gyrocotylideans, and caryophyllideans) lack proglottids and also possess only a single set of male and female reproductive organs rather than multiple sets (i.e., they are monozoic rather than polyzoic). The members of one order of tapeworms, the spathebothriideans, lack distinct proglottids but possess multiple sets of reproductive organs arranged in a linear series (i.e., they are nonproglottized but polyzoic). The majority of tapeworms, however, are proglottized, and each proglottid bears one or more sets of reproductive organs (i.e., they are proglottized and polyzoic). In proglottized tapeworms, a germinitive region located directly behind the scolex consecutively produces the proglottids of the strobila. Thus, the proglottid nearest the scolex is the youngest, and that furthest from the scolex is the oldest. In some tapeworms, the posterior-most proglottids, on reaching a certain level of maturity, drop from the strobila (apolytic) and may continue development independent of the main body of the worm. In other tapeworms, the proglottids are retained on the strobila essentially throughout the life of the animal (anapolytic). In the former instance the proglottids may complete the production of eggs independent of the strobila; in the latter case proglottids on the strobila produce eggs that are released through uterine pores or tears. Degrees of apolysis are often recognized. Thus, cestodes that drop mature proglottids are considered to be euapolytic; those that drop immature proglottids are considered to be hyperapolytic. Proglottids filled with eggs are termed gravid. Consecutive proglottids either overlap (craspedote) or not (acraspedote). A very few species exhibit proglottids that, rather than being hermaphroditic, are either male or female. Because these proglottids are found on the same strobila, individuals of these species are considered to be hermaphroditic, but the proglottids themselves are not. There is, however, evidence of gonorchorism (separate sexes) in individuals of a few tapeworm species in which all of the proglottids of the strobila are either entirely male or entirely female.

With at least 751 recognized genera, the cestodes are the second most diverse group of platyhelminths. The most recent comprehensive systematic treatment of the group is that of Khalil *et al.* (1994), in which 14 orders were recognized. However, since then, the class has been revised to consist of 18 orders. The bothriate tapeworm orders are considered to be earlier divergent lineages than the acetabulate tapeworm orders (i.e., those with suckers or bothridia), but the relationships among the acetabulate orders remain controversial, as does membership in some of the elasmobranch-parasitizing orders.

The terms Cestoidea, Cestodaria, and Eucestoda are also sometimes used in reference to tapeworms. The term Cestoidea is synonymous with the term Cestoda; the authors have followed Hyman (1951) and Grassé (1961) in using the term Cestoda here. In the past, the amphilinideans and gyrocotylideans have been collectively referred to as the Cestodaria. However, evidence against the monophyly of this group is mounting, and, thus, the Cestodaria is not recognized here. The term Eucestoda is used to collectively refer to the cestodes other than the amphilinideans and gyrocotylideans. The monophyly of the Eucestoda is fairly well accepted; members of this subclass can be distinguished from the amphilinideans and gyrocotylideans, for example, in their possession of a scolex and also in that their sperm lack mitochondria.

To make the following diagnoses more concise, unless otherwise indicated, it should be assumed that an order possesses an anterior scolex of some form, lacks all vestiges of a digestive system, and possesses a strobila consisting of numerous proglottids that each contain one full set of both male and female reproductive organs (polyzoic). These proglottids contain numerous, compact testes filling much of the region anterior to the ovary, sperm lacking a mitochondrion, flagella that are incorporated into the main body of sperm, $9+'1'$ microtubule arrangement in the flagella of the sperm, a cirrus

armed with microtriches, a cirrus-sac, a single posterior ovary, a vitellarium consisting of numerous follicles that extend in two lateral bands, one down each side of the proglottid, a Mehlis' gland located posterior to the ovarian bridge, a uterus that is sacciform, and male and female systems that open through a combined lateral genital pore, with pores of consecutive proglottids alternating irregularly down the length of the strobila.

Amphilinidea

See Figure 53 (**Plate 4**). Distinct scolex absent but with anterior coniform "sucker;" one set of male and female reproductive organs (monozoic) present; testes in two lateral bands; sperm with mitochondrion; cirrus-sac absent, ovary varying in shape; preformed uterine pore anterior; uterus often N-shaped or sinuous; seminal receptacle present; genital pores usually separate, posterior.

Habitat: Adults parasitic in body cavity of chondrosteans, some freshwater and marine teleosts, and Australian freshwater turtles.

Gyrocotylidea

See Figure 54 (**Plate 4**). Distinct scolex absent but with anterior "sucker," rosette usually present at posterior end of body; body usually "spined" (spines are likely to be microtriches), "spines" limited in distribution or not; excretory system reticulate; one set of male and female reproductive organs (monozoic) present; sperm with mitochondrion; cirrus-sac absent; ovary follicular, in V- or U-shaped band around seminal receptacle; seminal receptacle present; uterus sinuous, in median region of anterior part of body, terminal portion expanded into sac, opening into preformed ventral uterine pore; genital pores separate, both anterior.

Habitat: Adults parasitic in spiral intestine of holocephalans.

Subclass Eucestoda

Bothriocephalidea

See Figure 55 (**Plate 4**). Small to large tapeworms; scolex with two lateral bothria, occasionally with posterior appendages, occasionally divided into two or several vertical loculi, with or without muscular apical disc, occasionally replaced by scolex deformatus or peudoscolex; each bothrium usually unarmed, occasionally armed with one pair of hooks or apical series of hooks; proglottization usually complete; proglottids usually craspedote, usually wider than long; anapolytic, usually with one set of male and female reproductive organs per proglottid, rarely with two sets per proglottid; cirrus unarmed or armed; combined genital pore dorsal, median, sublateral or lateral, irregularly alternating; ovary posterior, medullary, mostly bilobed; vitelline follicles usually cortical, medullary or both, in two extensive lateral bands or circumsegmental; uterus variable, consisting of winding uterine duct and compact or diverticulate uterine sac; preformed uterine pore present or absent, if present opening posterior to genital pore.

Habitat: Adults parasitic in intestine of teleosts, rarely salamanders.

Caryophyllidea

See Figure 56 (**Plate 4**). Scolex usually with one to three pairs of weakly developed shallow depressions or grooves (considered to be loculi if temporary, bothria if more permanent), occasionally with terminal introvert or disc; with one set of male and female reproductive organs (monozoic); ovary H- or dumbbell-shaped; vitellarium usually preovarian, occasionally postovarian follicles also present; seminal receptacle present or absent; uterus often sinuous; female pore a combined utero-vaginal pore; genital pores separate or combined, median, ventral.

Habitat: Adults parasitic in intestine of siluriform and cypriniform freshwater fishes.

Cathetocephalidea

See Figure 57 (**Plate 4**). Large worms; scolex in form of single transversely expanded fleshy organ, lacking all signs of acetabula, bothria, and armature; usually with one strobila per scolex, rarely with multiple strobilae per scolex; proglottids acraspedote, euapolytic; with one set of male and female reproductive organs per proglottid; testes in single field; ovary H-shaped in dorso-ventral view; vitelline follicles circumsegmental; preformed uterine pore absent; vagina extending anterior to cirrus-sac; combined genital pore lateral; genital pores alternating irregularly along length strobila.

Habitat: Adults parasitic in spiral intestine of whaler sharks.

Cyclophyllidea

See Figure 58 (**Plate 4**). Scolex usually with four round suckers; suckers armed with spines or not; often with apical organ in form of single sucker (rarely four apical suckers), some with apical, often protrusible rostellum; rostellum armed with one or two rings of hooks or not, with or without rostellar pouch; scolex divided into scolex and metascolex, or with pseudoscolex in some; proglottids craspedote or acraspedote;

Plate 4 Cestoda (Figures 53–70) 53. Amphilinidea: adult of *Amphilinia* sp. (Gibson in Khalil, *et al.*, 1994); 54. Gyrocotylidea: adult of *Gyrocotyle* sp. (Gibson in Khalil, *et al.*, 1994); 55. Bothriocephalidea: adult of *Bathycestus brayi.* (Kuchta and Scholz, 2004); 56. Caryophyllidea: adult of *Paraglaridacris* sp. (Mackiewicz in Khalil, *et al.*, 1994); 57. Cathetocephalidea: adult of *Sanguilevator yearsleyi*; 58. Cyclophyllidea: adult of *Echinococcus* sp.; 59. Diphyllidea: adult of *Echinobothrium* sp.; 60. Diphyllobothriidea: adult of *Diphyllobothrium* sp.; 61. Haplobothriidea: adult of *Haplobothrium* sp.; 62. Lecanicephalidea: adult of *Corrugatocephalum* sp.; 63. Litobothriidea: adult of *Litobothrium daileyi*; 64. Nippotaeniidea: adult of *Nippotaenia* sp. (Bray in Khalil, *et al.*, 1994); 65. Proteocephalidea: adult of *Proteocephalus* sp.; 66. Rhinebothriidea: adult of *Rhinebothrium megacanthophallus*; 67. Spathebothriidea: adult of *Spathebothrium* sp.; 68. Tetrabothriidea: adult of *Tetrabothrius* sp.; 69. "Tetraphyllidea": adult of *Acanthobothrium* sp.; 70. Trypanorhyncha: adult of *Pterobothrium* sp. Abbreviations: APO, apical organ; AS, apical sucker; BO, bothrium; BOD, bothridium; CGP, common genital pore; CPE, cephalic peduncle; CPS, cruciform pseudosegments; FP, female genital pore; GP, gravid proglottid; H, hook; IMP, immature proglottid; L, loculus; MA, muscular appendage; MB, muscular bulb; MP, male genital pore; MPR, mature proglottid; MUP, muscular pad; PA, pars apicalis; PB, pars basalis; PRG, proglottid; PSC, primary scolex; PST, primary strobila; R, rosette; RO, rostellum; S, sucker; SCO, scolex; SK, stalk; SSC, secondary scolex; SST, secondary strobila; STR, strobila; TE, tentacle; TS, tentacle sheath; U, uterus; UP, uterine pore.

apolytic or anapolytic; usually with one but rarely two strobilae per scolex; usually with one but occasionally two sets of male and female reproductive organs per proglottid; strobila rarely with proglottids that are entirely either male or female, or male and female proglottids that alternate regularly along strobila; testes, one to many, usually anterior to ovary, occasionally posterior to ovary; cirrus-sac usually present; cirrus usually armed with spiniform microtriches, occasionally with stylet, occasionally with accessory sac; external and internal seminal vesicles present or absent; ovary dumbbell-shaped, or asymmetrical; vitellarium usually single compact mass, occasionally bilobed mass, usually posterior to ovary; vagina present or absent, replaced functionally by cirrus-sac and modified male duct, or replaced by supplementary ducts running between seminal receptacles in consecutive proglottids in some taxa; uterus ring-shaped, or saccate, with or without lateral branches (diverticula), or reticular, transverse in some, replaced by parauterine organ(s) in some, replaced by uterine capsules or parenchymatous egg capsules in some, uterus single or double, usually with preformed uterine pore; common genital pore lateral, rarely midventral; genital pores occasionally regularly alternating or unilateral along strobila; genital atrium conspicuous or not, with or without prominent radial musculature; vagina usually posterior to cirrus-sac, occasionally dorsal to ventral to cirrus-sac.

Habitat: Adults parasitic in intestine of amphibians, snakes, lizards, birds, or mammals.

Diphyllidea

See Figure 59 (**Plate 4**). Scolex with two bothria, proximal surfaces of bothria occasionally with spines; scolex with apical organ; apical organ usually armed with one row of large hooks on dorsal and ventral surfaces, often with continuous or interrupted row of smaller hooklets on lateral margins, occasionally with small spines; bothria supported by cephalic peduncle; cephalic peduncle often armed with eight columns of straight hooks with trifid bases; proglottids acraspedote; generally apolytic; testes usually filling proglottid anterior to ovary; ovary H-shaped in dorso-ventral view; lateral bands of follicles of vitellarium occasionally extending medially; preformed uterine pore absent; vagina posterior to cirrus-sac; common genital pore median, ventral.

Habitat: Adults parasitic in spiral intestine of rays, skates, and sharks of families Hemiscyllidae, Scyliorhinidae, and Triakidae (most marine).

Diphyllobothriidea

See Figure 60 (**Plate 4**). Medium to large tapeworms; scolex with two bothria (one dorsal and one ventral), occasionally with posterior appendages, occasionally divided into two or several vertical loculi, with or without muscular apical disc, unarmed; proglottization usually complete; proglottids craspedote or acraspedote, usually wider than long; anapolytic, usually with one set of male and female reproductive organs per proglottid, but occasionally multiple sets per proglottid; cirrus-sac usually thin-walled; cirrus unarmed; genital pore ventral, median, or submedian; ovary, posterior, medullary, mostly bilobed; vitelline follicles usually cortical and circumsegmental; uterus in form of spiral tube; preformed uterine pore opening posterior to genital pore.

Habitat: Adults parasitic in intestine of tetrapods, mostly mammals.

Haplobothriidea

See Figure 61 (**Plate 4**). Body bearing primary and secondary scoleces and strobila; primary scolex with four tentacles with spiniform microtriches at bases, each tentacle with muscular sac into which it can be withdrawn, bothria, bothridia and suckers absent; primarily strobila proglottized, but primary proglottids never develop reproductive organs on primary strobila; proglottized regions of primary strobila separate from remainder of primary strobila and develop into secondary strobilae that produce proglottids, each proglottid bearing one set of reproductive organs; anterior-most proglottid of each secondary strobila modified as secondary scolex; secondary scolex with four shallow anterior indentations surrounding central, apical dome; cirrus-sac median, anterior, cirrus armed with microtriches; testes numerous, arranged in two lateral fields; ovary inverted U-shaped; follicles of vitellarium arranged in two lateral fields, confluent in midline at anterior and posterior regions of proglottid; uterus with dilated uterine sac; preformed uterine pore present or absent; vagina posterior to cirruss-sac; seminal receptacle present; genital pores separate, median, anterior; eggs operculate.

Habitat: Adults parasitic in intestine of the bowfin, *Amia calva*.

Lecanicephalidea

See Figure 62 (**Plate 4**). Scolex usually divided into two parts: if present an anterior region (pars apicalis) variable in form, elongate (myzorhynchus), pad-like (metaporhynchus), sucker-like, or consisting of a crown of nonhooked tentacles; posterior region (pars basalis) usually cushion-like, often bearing four circular suckers or bothridia; proglottids, craspedote or acraspedote, usually apolytic; testes, three to many, arranged in a single or multiple columns; external seminal vesicle usually present, often conspicuous, extending to near posterior margin of proglottid; ovary bilobed, multilobed or irregular in dorso-ventral view; follicles of vitellarium sometimes encircling proglottid; preformed uterine pore absent; vagina present or absent, almost always posterior to cirrus-sac; cirrus armed or not; combined genital pore lateral; genital pores alternating irregularly along length strobila.

Habitat: Adults parasitic in spiral intestine of marine elasmobranchs, primarily rays.

Litobothriidea

See Figure 63 (**Plate 4**). Worms small; scolex with cup-shaped apical sucker and three to five pseudosegments, some pseudosegments cruciform, with or without posterior spine-like structures; proglottids slightly craspedote, euapolytic; testes arranged in two to multiple columns; cirrus armed; ovary inverted U-shaped in dorso-ventral view; vitelline follicles encircling proglottid; preformed uterine pore absent; vagina opening at same level as cirrus-sac; combined genital pore lateral; genital pores alternating irregularly along length strobila.

Habitat: Adults parasitic in spiral intestine of marine lamniform sharks.

Nippotaeniidea

See Figure 64 (Plate 4). Scolex in form of single apical sucker; proglottids acraspedote, anapolytic or apolytic; testes restricted to previtelline medulla of proglottid; cirrus-sac thin-walled; convoluted ejaculatory duct present; seminal vesicle present or absent; ovary dumbbell-shaped in dorso-ventral view, vitellarium consisting of two symmetrical compact masses, anterior to ovary; uterus in form of transverse coils in medulla, lacking preformed uterine pore; vagina opening posterior to cirrus-sac.

Habitat: Adults parasitic in digestive system of freshwater teleosts.

Proteocephalidea

See Figure 65 (Plate 4). Scolex usually with four round suckers or bothridia; suckers or bothridia uni-, bi-, tri-, or tetra-loculate; apex of scolex sometimes with armed rostellum, or large sucker, or occasionally with apical organ in form of two lappets; metascolex sometimes present as wrinkled region posterior to suckers that may or may not cover suckers of scolex; scolex with or without gland cells; proglottids craspedote or acraspedote, usually anapolytic; longitudinal muscle bundles usually conspicuous, occasionally inconspicuous; ovary usually dumbbell-shaped in dorso-ventral view; uterus usually with lateral branches (diverticula) when gravid, opening through one or more longitudinal apertures; vagina usually anterior to, but occasionally posterior to, cirrus-sac; genital pores rarely separate, lateral, alternating irregularly along length strobila; distinction between cortex and medulla usually marked.

Habitat: Adults parasitic in intestine of freshwater teleosts, occasionally in amphibians, terrestrial lizards (such as, e.g., *Varanus*, monitor lizards) and snakes.

Rhinebothriidea

See Figure 66 (Plate 4). Small to medium worms; scolex with four stalked, unarmed bothridia with facial septa; with or without myzorhynchus and marginal septa; proglottids craspedote or acraspedote, generally euapolytic; post-poral testes usually lacking; cirrus armed; ovary H-shaped in dorso-ventral view; vitelline follicles usually in two lateral fields, occasionally encroaching on median line; preformed uterine pore absent; vagina opening anterior to cirrus-sac; combined genital pore lateral; genital pores alternating irregularly along length strobila.

Habitat: Adults parasitic in spiral intestine of marine and freshwater batoid elasmobranchs.

Spathebothriidea

See Figure 67 (Plate 4). Scolex usually bearing one or two sucker-like attachment organs, but occasionally absent; osmoregulatory system in form of canals on each side of strobila, with irregular commissures and lateral pores; body proglottization absent; with multiple sets of male and female reproductive organs serially repeated down body (polyzoic); testes in two irregular lateral bands that extend throughout the length of the body; ovary rosette-shaped or bilobed, median, posterior to genital pores; small seminal receptacle occasionally present; uterus often sinuous, with median pore; male and female pores separate, opening close to one another along median line, usually irregularly alternating in adjacent proglottids between opening dorsally and ventrally.

Habitat: Adults parasitic in intestine of freshwater, brackish water and marine chondrosteans and teleosts.

Tetrabothriidea

See Figure 68 (Plate 4). Scolex usually with four muscular bothridia; bothridia round, rectangular or occasionally triangular in form, often with auriculate muscular appendages; auricles sometimes fused to form apical "organ;" apical rostellum present or absent; proglottids craspedote; anapolytic; testes, few to many; ovary bilobed or highly lobed in dorso-ventral view; vitellarium in form of single compact mass, usually anterior to ovarian bridge; uterus transverse, with one or more dorsal pores; seminal receptacle present or absent; vagina occasionally armed; genital pores combined or not; genital atrium often muscular, sometimes with distinct male atrial canal, or genital papilla, occasionally armed; genital pores usually unilateral along length of strobila; vagina usually posterior to cirrus-sac.

Habitat: Adults parasitic in intestine of seabirds, pinnipeds, and cetaceans.

"Tetraphyllidea"

See Figure 69 (Plate 4). Scolex divided into four muscular sessile or pedunculated bothridia of a variety of forms; bothridia with or without apical muscular pad, with or without one or two pairs of uni, bi, or tripronged hooks, may or may not be further subdivided into loculi; muscular pad with or without one or three accessory suckers; metascolex occasionally present; proglottids craspedote or acraspedote, generally euapolytic; rarely with proglottids that are either male or female (or female proglottids retain male copulatory apparatus); ovary usually H-shaped, occasionally A-shaped in dorso-ventral view; vitelline follicles sometimes completely encircling proglottid, rarely condensed around ovary; uterine pores sometimes present, but not preformed, or uterus opening through median slits in uterine wall; vagina opening anterior to cirrus-sac; genital pores rarely separate, alternating irregularly or rarely unilateral along length of strobila. The order is almost certainly not monophyletic as currently configured.

Habitat: Adults parasitic in spiral intestine of marine and freshwater elasmobranchs or very rarely holocephalans.

Trypanorhyncha

See Figure 70 (Plate 4). Scolex with four retractable, hollow tentacles each armed with numerous spiral rows of hooks (hook patterns of enormous taxonomic importance); each tentacle everted and retracted by rhyncheal apparatus consisting of tentacle sheath, and retractor muscle originating within posterior muscular bulb (tentacles and rhyncheal apparatus rarely absent); scolex with two or four bothria and elongated peduncle housing rhyncheal apparatus; proglottids craspedote or acraspedote, apolytic or anapolytic; usually with one set of male and female reproductive organs per segment, but occasionally with two sets; cirrus-sac or hermaphroditic-sac usually present; external, internal and accessory seminal vesicles present or absent; ovary usually H-shaped in dorso-ventral view; follicles of vitellarium lateral or completely

encircling proglottid; uterus tubular or branched, with or without preformed uterine pore; vagina usually opening posterior to cirrus-sac, occasionally dorsal or ventral to cirrus-sac; common genital pore often associated with muscular lips.

Habitat: Adults parasitic in spiral intestine, stomach, rarely gall bladder, of elasmobranchs.

Nervous System

A bewildering variety of neural organization and complexity characterizes the platyhelminths (e.g., see Halton and Gustafsson, 1996). The basic plan involves an apical subepidermal brain consisting of multiple neurons, which can be uni, bi (especially in Neodermata), or multilobed. This is a true brain because it controls reflexes in the peripheral nerve net. The number of nerve cells (neurons) in the brain varies between 50 and 550 in free-living species, but this number is less well known for the neodermatans. The brain is generally connected to two, or sometimes more, main longitudinal nerve cords, each consisting of axons with cell bodies distributed at irregular intervals along the length of the cords. These main nerve cords are usually connected to one another by numerous transverse commissures in a ladder-like arrangement. In addition, a peripheral array of nerve plexuses (or nerve-nets) is found throughout the body. The attachment organs and the components of the female reproductive system involved in egg formation are especially well supplied with nerve plexuses, but plexuses are also found associated with the pharynx and intestine and below the surface and below the muscle layers of the body. There are separate plexuses for sensory, integrative and motor activities. The central nervous system (brain plus main cords) is more emphasized in neodermatan groups than in non-neodermatan groups. Cestodes may exhibit regional differences in the complexity of the subtegumental plexuses along the length of the body. Transmission electron microscopy suggests that platyhelminths exhibit an extensive diversity of types of sensory receptors.

Several different neuronal cell types are present, including unipolar, bipolar, and multipolar cells. Although unipolar neurons are generally confined to the ganglia of the brain and longitudinal nerve cords, cells of plexuses are dominated by bipolar cells. Individual neurons are highly secretory and contain a variety of types of vesicles in their cytoplasm. Platyhelminths utilize a diversity of signaling molecules and at least two different groups of neuropeptides. The nervous systems of platyhelminths appear to possess compounds similar to all of the major neurotransmitters known in taxa as complex as vertebrates. In addition, there are two groups of neuropeptides that appear to be unique to flatworms: neuropeptide F and FMRPamide-related peptides (FaRPs) both of which are fairly extensively distributed among the various platyhelminth groups. The existence of glial or glial-like cells in platyhelminths remains somewhat controversial.

Feeding and Digestion

Other than a few fecampiids, dalyelloids, and the cestodes, flatworms generally have a digestive system divisible into a foregut and a caecum. The foregut leads from the mouth to the blind-ended sac-like caecum that is lined with a thin gastrodermis. Free-living species tend to be microphagous or predatory and feed on bacteria, unicellular alga, protists, and almost all types of invertebrates. Characteristically, the free-living species have a highly muscular suctorial pharynx. Depending on the species, the pharynx can be protruded, inserted, applied to, extended over, or used to envelop and swallow whole the various foodstuffs they actively seek or encounter. Food passes from the mouth *via* the pharynx to the esophagus and then to the caecum. The gastrodermis has glandular and phagocytic cells that digest and incorporate the nutrients. A number of free-living platyhelminths (e.g., prolecithophorans, rhabdocoels, polyclads) harbor endosymbiotic algae that serve as an additional source of food. The solid waste products of free-living species are often released *via* a genitointestinal canal, rather than a separate anus; in some groups (e.g., polyclads), anal pores assist with this function.

Symbiotic and parasitic platyhelminths vary their feeding habits according to the hosts on, or in, which they live. Groups that possess suckers may have numerous secretory cells and sensory structures surrounding the mouth and sucker. Although similar in basic design to the foregut of free-living groups, the parasitic groups tend to exhibit distinct cell type configurations in the gastrodermis. In these groups, the junction between the foregut and caecum is invariably abrupt. Aspidogastreans have a single cell type in their gastrodermis that alternates cyclically between a secretory–absorptive phase and an autophagic–exocytotic phase. Digeneans have a syncytial or cellular gastrodermis with only one cell type, and digestion takes place extracellularly in the lumen of the caecum. There is evidence, however, that some digeneans are capable of acquiring nutrients directly through microvillar extensions of their body surfaces. In contrast, digestion in the caecum of monogeneans is intracellular. The polyopisthocotylean monogeneans are blood-feeders. The nonpigmented cells in these taxa are thought to support and protect the pigmented digestive cells in the gastrodermis. In addition, at least some of these taxa possess a buccoesophageal canal between the buccal cavity and the esophagus that permits regurgitation of intestinal contents. The monopisthocotyleans feed on the epidermal cells and mucus of their host and have only a single gastrodermal cell type involved with endocytosis and digestion.

In the Cestoda and some symbiotic fecampiids all vestiges of a digestive system have been lost. These species rely solely on acquiring nutrients through their outer body wall. Among the Cestoda, and indeed all other neodermatans, the neodermis plays an active role in the biochemical transport of nutrients. In cestodes the surface area of the neodermis is markedly increased by the presence of microtriches, which enhance the availability of readily available nutrients to be actively absorbed into the parasite's body.

Excretion and Osmoregulation

The excretory system of platyhelminths is thought to function primarily in osmoregulation, with the removal of metabolic

wastes generally occuring by way of diffusion through the outer body layer. However, removal of excess water can also be achieved through the gut, and in free-living species it is not uncommon to find excretory products stored in various tissues. In platyhelminths, this system is made up of a series of protonephridia and is thus commonly referred to as a protonephridial system. It consists of a series of protonephridia connected to collecting ducts that empty into one or more major canals termed nephridioducts; these either open to the outside of the body through one or more nephridiopores or empty into a common excretory vesicle which opens to the outside through a common nephridiopore. All protonephridia consist of at least one flame bulb bearing two to many cilia, and a canal cell and sometimes also a cap cell. Rohde (1991) recognized three distinct types of protonephridia. In Type 1, found only in catenulids, each flame bulb has a cap cell, lacks a canal cell, and bears only two cilia, the rootlets of which extend along the collecting weir. In Type 2, found in most platyhelminths and also many other phyla including nemertines and gnathosomulids, each flame bulb has a cap cell and multiple cilia, the rootlets of which extend into the cap cell; each flame bulb is also associated with a canal cell that it may share with other flame bulbs. In Type 3, found only in kalyptorhynchs, "dalyellioids," temnocephalids, and potentially also "typhlophanoids" and the "lecithoepitheliatans," each flame bulb bears multiple cilia, but lacks a cap cell; each flame bulb is also associated with a canal cell that it usually shares with other flame bulbs. In all cases, the flame bulb is associated with a filtering apparatus, called a weir, which consists of processes of the cap and canal cell that are surrounded by a membrane. The beating of the cilia in the flame bulb draws body fluids across the membrane of the weir into the collecting ducts. One or two sets of protonephridia are present in all platyhelminths except a few catenulids in which excretion is thought to take place solely through the digestive syncytium. The protonephridial system is most developed in freshwater species. Indeed, this system is considered to have played a major role in allowing platyhelminths to invade freshwater habitats.

The protonephridial system of most platyhelminth taxa is paired (but the pairs are sometimes connected medially), consisting of two nephridioducts, one running along the lateral margin of each side of the body; these ducts connect to many protonephridia throughout their length. Some of the catenulids are exceptional in their possession of a single dorsal nephridioduct that opens through a single posterior nephridiopore; some proseriatans also possess a single set of protonephridia, but some possess three sets of protonephridia. In most of the non-neodermatan groups, the two nephridioducts open to the outside of the body through separate nephridiopores that are found in the anterior half of the body, generally on the ventral surface. In most temnocephalideans, the two nephridioducts open into separate, saccate excretory vesicles, located in the anterior of the body on either side of the pharynx, and the left and right sets of protonephridia are generally connected by two transverse ducts, one at the anterior and one at the posterior aspect of the system. The protonephridial system of monogeneans is similar to that of temnocephalidans, but the anterior transverse duct is absent in the polyopisthocotyleans.

The aspidogastreans possess a protonephridial system that is also much like that of the temnocephalidans but without the transverse ducts. The protonephridial system of digeneans differs somewhat from that of the aspidogastreans in that the two nephridioducts generally open into a common posterior excretory vesicle. This vesicle takes on a number of different forms in different taxa; for example, it can be V-, Y-, or I-shaped. Unlike other platyhelminth taxa, the arrangement of the protonephridia relative to the nephridioducts is regular and consistent in the cercarial stage of digeneans among individuals of the same species, but differs among individuals of different taxa, and thus this "flame cell formula" is often of significant taxonomic value. The larger number of flame bulbs and the difficulty of seeing most of the elements of the protonephridial system in the more robust bodies of the adult digeneans reduce the taxonomic utility of the flame bulb arrangement in adults.

Among tapeworms, the amphilinideans possess a protonephridial system consisting of a network of collecting ducts, rather than just two lateral nephridioducts. This network empties into an elongated excretory vesicle that opens to the outside through a posterior nephridiopore. The flame bulbs are usually found in pairs, grouped in clusters throughout the length of the body. The gyrocotylidean system also includes two longitudinal nephridioducts that are connected to one another by a number of secondary canals. The main nephridioducts open into a nephridiopore on the dorsal surface in the anterior half of the body. In most of the other cestode groups the protonephridial system consists of two dorsal and two ventral longitudinal nephridioducts, the ventral ducts generally being larger in diameter than the dorsal ducts; the nephridioducts are connected to multiple flame bulbs throughout the length of the body. Some cestodes do, however, have up to 12 longitudinal ducts. The pairs of dorsal and ventral nephridioducts are connected to one another in the scolex, where they may undergo extensive winding. The left and right nephridioducts are often connected to one another by way of transverse excretory ducts located in the posterior end of each proglottid; this condition is most commonly found in anapolytic eucestode species. In some groups, the longitudinal vessels are connected to one another with numerous lateral nephridioducts, resulting in a network-like arrangement of vessels. In the first proglottid formed (located at the posterior end of the strobila) the ventral pair of nephridioducts often empty into a small vesicle at the posterior end of this proglottid. However, once this proglottid drops from the strobila, the ventral vessels open to the outside separately in the posterior end of the terminal proglottid of the strobila. Rohde (1991) provides a useful overview of the evolution of the protonephridial system in platyhelminths.

Reproduction

Most platyhelminth species undergo sexual reproduction. Given the predominance of hermaphroditism in this phylum, there is some question about the relative frequency and importance of self- versus cross-fertilization in most species. In the few taxa in which this issue has been investigated in detail, cross- rather than self-fertilization appears to be the dominant

form of sexual reproduction. Gonochorism does, however, occur in some triclads, rarely in prolecithophorans, in a few fecampiids (e.g., *Kronborgia*), within the digenean family Schistosomatidae, and in a few tetraphyllidean and cyclophyllidean cestodes. To date, no instances of gonochorism in aspidogastreans or monogeneans are known. Most platyhelminths are simultaneous hermaphrodites, each individual possessing a full complement of male and female reproductive systems. There is a general tendency for the male system to mature before that of the female (protandry). Sperm transfer usually occurs during copulation. But, in a few species of macrostomids, catenulids, triclads, polyclads, rhabdocoels, polyopisthocotylean monogeneans, and cestodes, sperm is injected directly through the body wall and then migrates through the body to the female reproductive organs. Fertilization is always internal.

Asexual multiplication in one form or another is also found in a number of platyhelminths, either in the adult or, most commonly in neodermatans, in one or more of the larval stages. Adults of many of the catenulids and macrostomids undergo forms of asexual multiplication either as paratomy (regeneration before fission) or as architomy (regeneration after fission). These phenomena result in a linear chain of individuals that eventually separate and each develop into a mature worm.

Some adult triclads possess the ability to regenerate complete individuals from, in some cases, a very small portion of the body of the original individual. For example, it is possible to divide an adult freshwater triclad posterior to the pharynx and produce two complete adult individuals. More dramatic is the ability of adults of species belonging to the triclad genus *Phagocata* to divide into a number of separate fragments, each of which subsequently encysts and develops into a complete adult worm. Their ability to regenerate has made freshwater triclads favored animals for studies in wound healing and developmental genetics. Asexual reproduction in the form of polyembryony occurs in a diversity of free-living groups such as the triclads, rhabdocoels, "lecithoepitheliatans," and rhabdocoels.

With the exception of the aspidogastreans, asexual multiplication is found in at least some members of all of the neodermatan groups. Although it is uncommon among the monogeneans, it is considered to be present in the form of sequential polyembryony (hyperviviparity) in some members of the order Gyrodactylidea. Rather than releasing eggs containing oncomiracidia, an adult can produce a second generation juvenile *in utero* (without sexual reproduction) that in turn can produce a third generation juvenile *in utero*, until one single individual may yield in excess of 20 individuals of the subsequent generation from within its own body, apparently without the intervention of a second individual or of gametes. As a result, the body of such asexually multiplying individuals in effect resembles a series of Russian dolls. There is evidence, however, of sperm in the seminal receptacle of some of these embryos, which has led some to question this as a truly asexual form of multiplication.

Digeneans typically undergo asexual multiplication in the larval stages that parasitize the first, usually molluscan, intermediate host. All digeneans possess one or more generations of sporocysts or one or more generations of rediae, or one or more generations of both sporocysts and rediae. Asexual multiplication occurs in the generation of all larval stages developing within any generation (mother or daughter) of both sporocysts and redia. This form of asexual multiplication, termed polyembryony, results in multiple genetically identical individuals of the subsequent larval stage that develop within the saccate body of the parent generation. Thus, first generation sporocysts (mother sporocyts) produce either multiple second generation sporocysts (daughter sporocyts) or multiple first generation redia (mother redia), which in turn produce multiple second generation redia (mother redia) or multiple second generation redia (daughter redia), respectively. Second generation sporocysts produce either multiple cercariae or multiple redia that then subsequently produce multiple cercariae.

In tapeworms, asexual multiplication occurs in the terrestrial members of the order Cyclophyllidea that develop through larval stages known as coeneri and hydatid cysts. The fluid-filled cavity of these larvae is lined with a layer of germinative tissue that produces multiple protoscoleces, in the case of coeneri, and daughter hydatids that in turn are lined with germinative tissue that produces multiple protoscoleces, in the case of hydatid cysts. Each protoscolex has the potential to become an adult worm. The reproductive potential in these groups is enormous, with the hydatid cysts of some species producing hundreds of thousands, perhaps even millions, of protoscoleces.

Ontogeny

There are a remarkable variety of larval forms found among the platyhelminths, especially within and among the classes of neodermatans. In general, the life cycle of each class of neodermatan (see Figures 71–73) is characterized by one or more unique larval stages (**Plate 5**). This diversity reflects the great

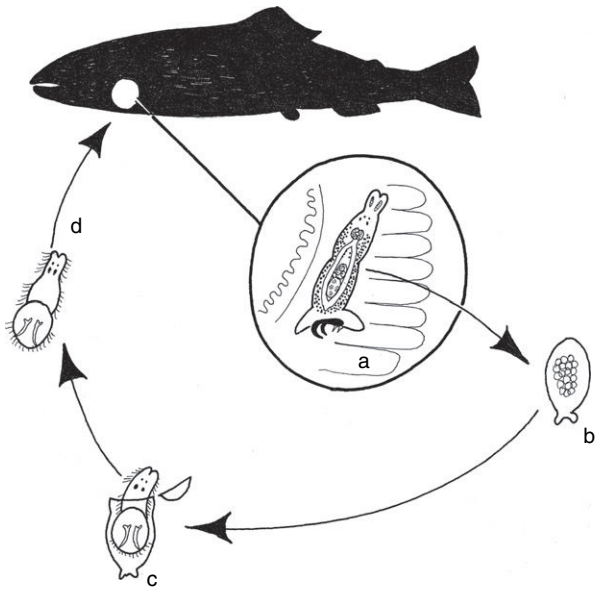

Figure 71 Generalized monogenean life cycle. (a) Adult on gills of definitive host (usually an aquatic vertebrate), undergoes sexual reproduction, and produces eggs; (b) eggs released into water; (c) oncomiracidium hatches from egg; (d) oncomiracidium finds definitive host.

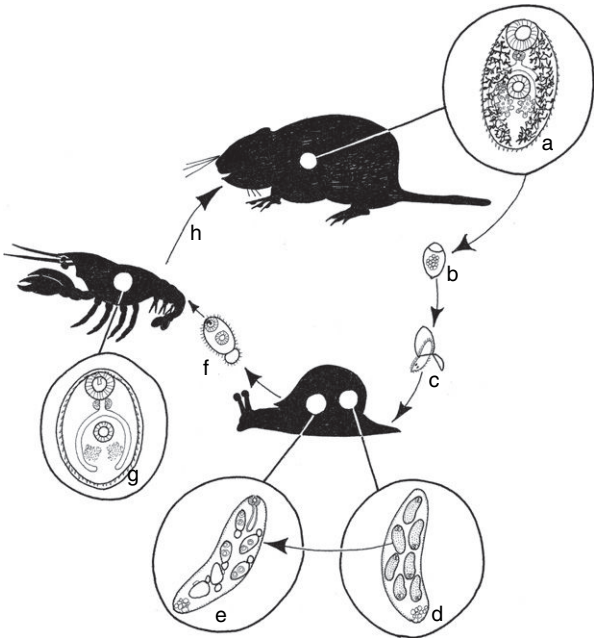

Figure 72 Generalized digenean life cycle. (a) Adult in definitive host, undergoes sexual reproduction and produces eggs; (b) eggs released with feces of host; (c) miracidium hatches from egg and penetrates first intermediate host (usually a mollusc); (d) miracidium develops into sporocyst containing numerous redia; (e) redia leave sporocyst and produce numerous cercariae; (f) cercaria escapes from first host and finds second intermediate host; (g) cercaria sheds tail, encysts, and develops into metacercaria; (h) second intermediate host containing metacercaria is eaten by definitive host.

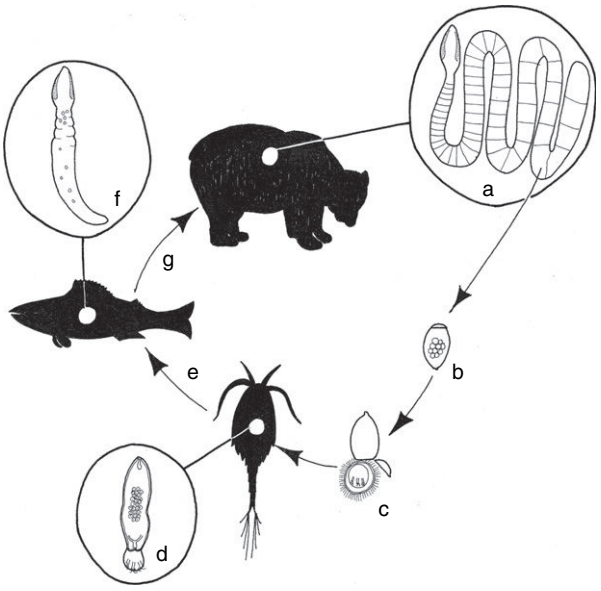

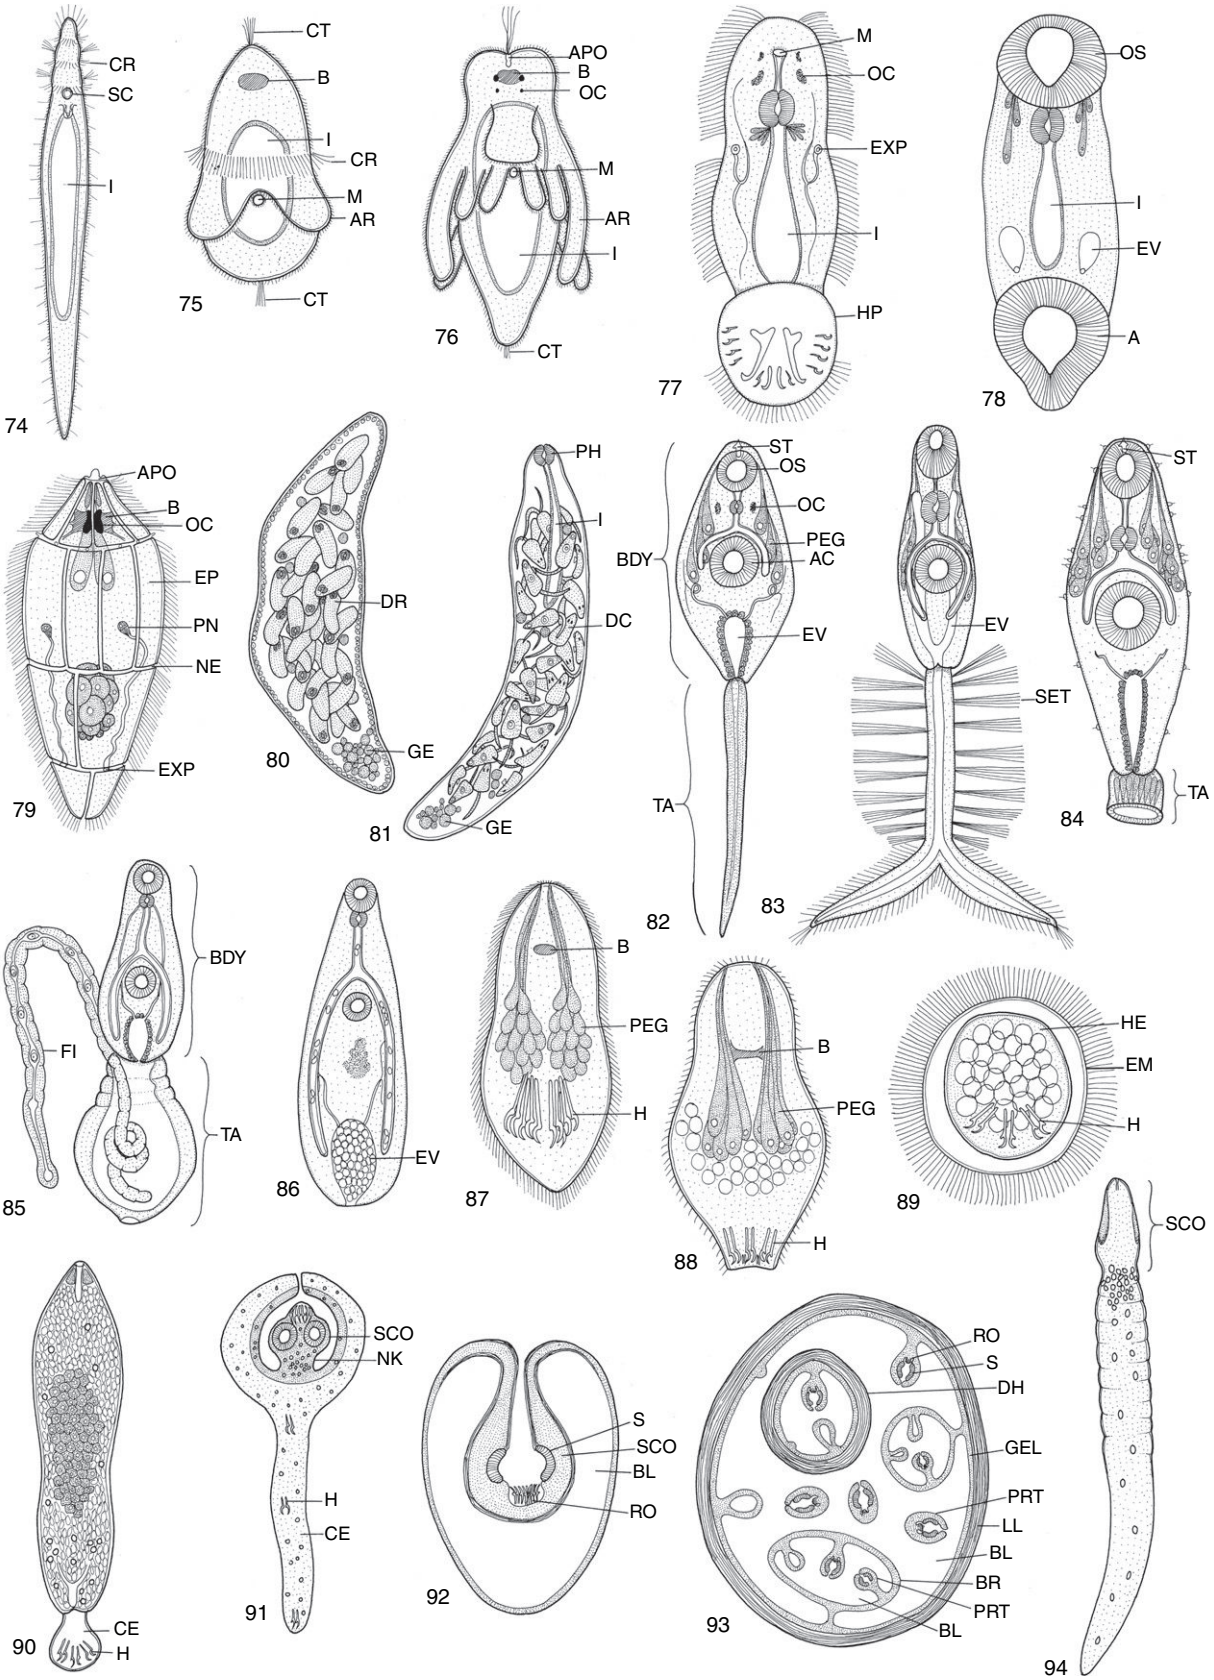

Figure 73 Generalized life cycle of aquatic cestode. (a) Adult in definitive host, undergoes sexual reproduction, and produces eggs; (b) eggs released with faeces of host; (c) coracidium larva hatches from egg and penetrates first intermediate host (usually a copepod); (d) coracidium develops into procercoid; (e) first host eaten by second intermediate host; (f) procercoid develops into plerocercoid; (g) second host eaten by definitive host (usually a piscivorous mammal).

range of habitats invaded and life history strategies employed. Most non-neodermatans undergo direct development such that the zygote develops directly into a form resembling a young adult. As discussed by Ruppert (1978), however, there are several notable exceptions to this pattern. One species of catenulid develops from a zygote into a pelagic larval stage known as a Luther's larva (Figure 74, **Plate 5**); the larva is vermiform in shape, ciliated throughout, but in addition possesses several anterior rings of elongate cilia that aid in swimming. The zygotes of some polyclads develop into free-swimming, ciliated larval stages bearing arms. These larvae are generally referred to as Götte's larvae (Figure 75, **Plate 5**) or Müller's larvae (Figure 76, **Plate 5**) depending on whether they possess four or seven to ten arms, respectively. This variation in developmental pattern is seen among individuals of some polyclad species. Götte's larvae are found only in members of the polyclad suborder Acotylea; Müller's larvae are known from members of both suborders of polyclads. There does not seem to be a phylogenetic pattern to the distribution of these larval stages among the polyclads. For example, the polyclad genus *Stylochus* includes species that develop into Götte's larvae, species that develop into Müller's larvae, and species that undergo direct development.

In general, the monogenean life cycle consists of two stages, the adult and a free-swimming larva, which is usually ciliated, known as the oncomiracidium. This larva usually possesses one or two pairs of ocelli, and is conspicuous in its possession of a posterior attachment structure known as a haptor, which is usually armed with hooklets (uncinuli) and sometimes also with hamuli (Figure 77, **Plate 5**). The oncomiracidium differs from the ciliated larvae of other neodermatans in that its cilia are often restricted to three distinct regions. When the oncomiracidium hatches from an egg, which is sometimes anchored to the substrate, it swims or creeps to find its vertebrate host. An oncomiracidial stage is mostly lacking from monogeneans such as the gyrodactylideans, which are unusually in that they are generally viviparous and undergo sequential polyembryony. A generalized oviparous monogenean life cycle is shown in **Figure 71**.

Prior to developing into the adult form, aspidogastreans pass through a larval stage called a cotylocidium (Figure 78, **Plate 5**), which is often but not always ciliated. This larval stage is free-swimming in at least some species. However, the life cycles of many species are not yet fully understood. In some cases it appears that the cotylocidium hatches from the egg and parasitizes the same host as the parent individual from which it was released. In other cases it appears that the cotylocidium hatches from the egg and moves into the water column to find a new host. In yet other cases the cotylocidium never hatches from the egg; rather, the egg is ingested by the molluscan host. In some species the life cycle is direct, involving only a single host. In other species, the life cycle may involve a second host which may be infected by ingesting infected molluscs.

Digeneans undergo complex development in which certain life cycle stages are able to produce multiple copies of new generations before becoming sexually reproductive adults. Consequently the term "larva" is used loosely when discussing life cycle stages in the Digenea. The digeneans pass through a series of larval stages that are either parasitic or free-living,

depending on their association with this sequence of hosts. A generalized digenean life cycle is illustrated in **Figure 72**. As can be seen, the basic sequence of larvae is as follows: miracidium, sporocyst, redia, cercaria, and metacercaria. The miracidium (Figure 79, **Plate 5**) possesses cilia on epidermal plates, or occasionally on tufts or bars. The neodermis is formed when the miracidium sheds its epidermal cell plates, thus all stages following the miracidium have an outer layer that is a neodermis. In most taxa the miracidium develops into a sporocyst, but it occasionally may develop into a redia. Sporocysts and redia are both sacciform. The main difference between them is that the sporocyst has none of the components of a digestive system (Figure 80, **Plate 5**), whereas the redia usually possesses at least a mouth, a pharynx, and often a single intestinal caecum (Figure 81, **Plate 5**). These stages vary morphologically among species in their possession of lateral lobes, and in some cases birth pores; the sporocysts of some species are branched. It is quite common for digeneans to possess more than a single sporocyt or redial generation in their life cycle. A first generation sporocyst (mother sporocyst) is essentially a miracidium that has lost its epidermal plates, whereas the second generation sporocysts (daughter sporocysts) are produced through asexual multiplication within the primary sporocyst. A first generation redia (mother redia) is most commonly produced through asexual multiplication within a primary or secondary sporocyst, but exceptionally develops directly from a miracidium that has shed its epidermal plates. Second generation rediae (daughter rediae) are produced through asexual multiplication within the primary redia). In most taxa, the final result of several generations of sporocysts or redia is the development of a number of cercariae. Each cercaria generally possesses an anterior body and a posterior tail. The cercaria is by far the most morphologically diverse of the digenean larval forms. Indeed, classification of the digenean families is based to a large extent on cercarial morphology. An elaborate nomenclature based on morphology exists to describe these cercarial types (e.g., see Cable, 1956). Examples of some of the more distinctive types include ophthalmoxiphidiocercaria (Figure 82, **Plate 5**), furcocercous (Figure 83, **Plate 5**), microcercous (Figure 84, **Plate 5**), and cystocercous cercariae (Figure 85, **Plate 5**). The metacercarial stage is usually achieved when the cercaria drops its tail and secretes a protective cyst around itself. The metacercaria is essentially a juvenile version of the adult worm (Figure 86, **Plate 5**). However, variations on this general developmental pattern occur: the metacercarial stage may be lacking or it may be preceded by an unencysted mesocercarial stage.

Associations of these larval forms with their hosts are quite predictable. In general, the miracidium and cercaria are free-living forms. The miracidium hatches from the egg and seeks the first (molluscan) host; the cercaria escapes from the mollusc and seeks either the second intermediate or the definitive host. The sporocyst and redial stages generally parasitize the first (molluscan) host. The metacercarial stage encysts either on aquatic vegetation or in or on the tissue of a second intermediate host, which can be either an invertebrate or vertebrate, depending on the digenean species. Exceptions to this general pattern do occur. In some species, the miracidium is not free-swimming; rather, it remains within the egg, which is subsequently eaten by the first host. In some species, the cercaria does not leave the mollusc to swim freely; rather, it continues its development into a metacercaria, encysting within the body of the sporocyst or redia within the molluscan host. In species that lack metacercaria, such as the schistosomes, the cercaria penetrates the tissues of the definitive host directly. This stage is referred to as a schistosomula once it drops its tail and enters the host.

Both amphilinideans and gyrocotylideans possess a ciliated larval stage known as a lycophore larva (Figure 87 and Figure 88, respectively; **Plate 5**). This larva possesses 10 hooks at the posterior end of its body; these hooks are of similar size and shape in gyrocotylideans but consist of six large and four small hooks, which also differ in shape, in the amphilinideans. This larval stage is also sometimes referred to as a decacanth. The life histories of many species in these two cestode groups are not well known. It appears that, in at least some amphilinideans, the lycophore does not escape from the egg until it is eaten by a small crustacean. In this intermediate host, the lycophore burrows through the gut and comes to rest in the hemocoel, where it develops into a procercoid by shedding its ciliated epidermal cells, elongating, and developing a posterior tail. It subsequently develops into a plerocercoid by shedding its tail and undergoing further elongation. In another case, the lycophore larva hatches and actively penetrates through the cuticle of the intermediate crayfish host. Development into the adult stage occurs only when the intermediate host is eaten by an appropriate vertebrate, at which point the plerocercoid sheds its tail and becomes sexually mature. It is possible that gyrocotylideans do not require an intermediate host to complete their development.

Most eucestodes require at least two hosts to complete their life cycles, but it is also common for additional paratenic hosts to occur in the life cycles of these platyhelminths. Paratenic hosts are not required, but serve to bridge food chain gaps,

thereby facilitating infection of appropriate vertebrate hosts. A generalized aquatic eucestode life cycle is illustrated in **Figure 73**. In general, eucestode zygotes initially develop into a larval stage known as a hexacanth embryo (Figure 89, **Plate 5**). This embryo characteristically possesses three pairs of hooks. The hexacanth may or may not be surrounded by a layer termed an embryophore. A hexacanth surrounded by an embryophore is referred to as an oncosphere. An oncosphere in which the outer region of the embryophore is ciliated is referred to as a coracidium and is usually free-swimming. Some cestode hexacanths or oncospheres are surrounded by an egg shell; this shell possesses a cap-like operculum in some groups. A hexacanth enters the first intermediate host either when it is eaten or by actively swimming to and then penetrating this first host. The first intermediate host is an invertebrate in most eucestode groups, but some terrestrial cyclophyllideans utilize vertebrate as first intermediate hosts. The developmental fate of the hexacanth remains to be discovered in many cestode species; this is especially true of the trypanorhynchs and tetraphyllideans. However, existing data suggest that, in general, the larval stages that follow the hexacanth vary somewhat in form among the different cestode orders. These forms are generally given different names depending on their morphology. The key features for distinguishing among larval types are the presence or absence of a scolex, the number of scoleces, whether the scolex (or scoleces) is invaginated (turned inside out) or retracted (withdrawn) into the main body of the larva, and whether a cavity known as a primary lacuna is present. Although current terminology does not accommodate all known combinations of these features, some common larval forms are given (see following). For example, procercoids are solid-bodied, lack a scolex, and usually possess a posterior extention of the body considered a cercomer by some (Figure 90, **Plate 5**). Plerocercoids possess a scolex that is neither invaginated nor retracted (Figure 94, **Plate 5**). Cysticercoids possess a conspicuous scolex that is retracted into the tissue of the neck alone, or, in some cases, the neck is then retracted into the main body of the larva (Figure 91, **Plate 5**). Cysticerci possess one (Figure 92, **Plate 5**), or more invaginated scoleces. Cysticerci with multiple scoleces are referred to as either hydatid cysts (Figure 93, **Plate 5**) or coeneri, depending on whether they have the ability to generate daughter cysts or not, respectively. The reproductive potential of hydatid cysts is enormous as each scolex (termed a protoscolex in hydatids) can go on to become either an adult worm or another protoscolex, if released from the original cyst within the first host. The numerous marine eucestode larvae referred to as "*Scolex pleronectes*" or "*Scolex polymorphus*" are likely to be the plerocercoid larvae of tetraphyllideans.

Phylogenetic Relationships

The tree shown in **Figure 1** provides an overview of the current understanding of the phylogenetic relationships among the major platyhelminth groups. The topology of this tree was derived from a combination of molecular analyses (e.g., Lockyer *et al*., 2003; Willems *et al*., 2006). The morphological characters that have been mapped onto the tree include distinguishing characters for some of the major groups as well as characters that potentially support the phylogenetic relationships shown. It is of note that, the Acoelomorpha (Acoela + Nemertodermatida), are no longer considered members of the Platyhelminthes; instead they are considered to be basal bilaterians or even early divergent deuterostomes, perhaps allied with the enigmatic *Xenoturbella*. The phylogenetic relationships of the platyhelminths in general are treated below. Readers are directed to Littlewood and Bray (2001) and Littlewood *et al*. (2004) for more detailed treatments of the phylogenetic relationships of individual groups.

In truth, few unique features (synapomorphies) have been identified for the phylum Platyhelminthes. None of the characters normally used to describe the group (i.e., dorsoventral flattening, acoelomate, bilateral symmetry) is unique to this group, nor are some of these characteristics (e.g., dorsoventral flattening) characteristic of all members of the group. A candidate synapomorphy for the phylum is the lack of accessory centrioles from the base of the cilia of the protonephridial flame bulbs, but unfortunately, this feature is visible only with transmission electron microscopy. The lack of sperm flagella is a condition seen in the three most basal platyhelminth orders (i.e., Catenulida, Macrostomida, and Haplopharyngida), but the remaining platyhelminth groups exhibit the much more widespread condition of biflagellated sperm.

Some morphological and recent molecular data appear to confirm the monophyly of many of the major platyhelminth groups but have highlighted the need for further systematic research. Although the nonmonophyly of the non-neodermatan platyhelminths, previously referred to collectively as the "turbellarians," is now well accepted, the relationships among the non-neodermatan platyhelminth orders remain poorly understood. There is general agreement that the catenulids represent the earliest divergent extant lineage of platyhelminths. The members of this order are exceptional in that they have lost their sperm flagellation and possess a single, rather than a paired, protonephridial system; they also possess protonephridia of Type 1 (i.e., with a cap cell, only two cilia, and no canal cell). In addition, the catenulids lack several distinctive features that unite most or all of the remaining playthelminths as a group referred to collectively as the Rhabditophora. For example, rhabditophorans and catenulids differ in the genetic codes they use to translate mitochondrial protein-coding genes; catenulids share the same mitochondrial code as other protostome invertebrates but rhabditophorans translate AAA as asparagine (usually lysine), and AUA as isoleucine (usually methionine). In addition, whereas most rhabditophorans possess rhabdites and the duogland adhesive system, the catenulids do not. All platyhelminths except the catenulids, macrostomids, and haplopharyngids share a unique arrangement of flagellar microtubules (9 + '1' rather than 9 + 2) in their sperm, which are biflagellated. All of the platyhelminths except most members of these three orders and the polyclads share the possession of an ovary that is heterocellular (rather than homocellular) and thus produce eggs that are ectolecithal (rather than endolecithal). With the exception of the "lecithoepitheliatans," this suite of heterocellular platyhelminths also possesses vitelline and ovarian cells that are arranged in separate organs, rather than combined into a single germinovitellarium. Apart from the fact that the polyclads

possess extensive branching of their intestinal caeca, temnocephalidans generally exhibit a series of anterior tentacles, and triclads exhibit an extra embryonic intestine, robust morphological synapomorphies for the non-neodermatan platyhelminth orders have not been forthcoming. The proseriatans lack the duogland adhesive system, but so do the temnocephalans and neodermatans. Prolecithophorans have lost their rhabdites, but so too have the temnocephalans and neodermatans. The fecampiids have lost their digestive system, but so too have the cestodes. Molecular data support recognition of the Kalyptorhynchia + "Dalyellioida" + Temnocephalida + "Typhyloplanida" as a monophyletic group, and, in fact, these four orders have collectively been referred to as the Rhabdocoela owing to their possession of a distinctive pharynx and barrel-like intestine. These four orders also share protonephridia of Type 3, but this feature is also found in the "lecithoepitheliatans." Also comprising a group supported by molecular data are the Prolecithophora, Tricladida, and Fecampiida; however, a morphological synapomorphy for this group remains to be identified.

The monophyly of the Neodermata, consisting of the monopisthocotyleans and polyopisthocotyleans (i.e., monogeneans) as well as aspidogastreans, digeneans, and the cestodes, is now among the most well-established aspects of platyhelminth relationships. The neodermatans are characterized by their possession of a unique syncytial outer body layer known as the neodermis, which generally replaces the cellular epidermis, and is shed when the first larval stage encounters the first host. In addition, the sperm of neodermatans is unusual among platyhelminths (except the kalyptorhynchs) in that the two flagella are actually incorporated into the cytoplasm of the sperm, rather than remaining separate. All neodermatans also lack rhabdites and the duogland adhesive system. The neodermatans are obligate parasites, most of vertebrates, at some time during their lives.

All Monogenea exhibit a posterior haptor. They are further unique among the platyhelminths in their possession of a ciliated larval stage known as the oncomiracidium (with the exception of the few viviparous forms) and also of four rhabdomeric ocelli at some point in their lives. However, the union of the two subclasses (Monopisthocotylea and Polyopisthocotylea) in the Class Monogenea is contradicted by molecular phylogenetic analysis of nuclear ribosomal RNA genes, and mitochondrial genomes, depending on the analysis and gene set; these molecular data suggest paraphyly of the monogeneans, with either Monopisthocotylea or Polyopisthocotylea as the earliest divergent neodermatan lineage. Nonetheless, the monophyly of each of these two subclasses appears to be robust. In each case it is supported by morphological features as articulated above and in the most extensive morphological phylogenetic treatment of the group (see Boeger and Kritsky, 2001). The nonmonophyly of the Class as suggested by molecular work may reflect a rapid divergence of the two subclasses rather than lack of support for monogenean monophyly. The interrelationships among the monogenean orders within these two subclasses are also not universally agreed on.

The Aspidogastrea, Digenea, and Cestoda are united by their complex life cycles. The close affinities between the Aspidogastrea and Digenea, collectively referred to by some as the Trematoda, are supported by their possession of epidermal cells in their first larval stage (cotylocidia and miracidia, respectively) that are separated from one another by portions of the neodermis. In addition, the first or primary host in the life cycle of the trematodes is a mollusc. The Aspidogastrea are unique in their possession of oviducts separated into chambers by septa and and also potentially in their possession of neodermal microvilli in the form of hemispherical microtubercles. The Digenea are distinctive in their possession of several unique larval stages, the miracidium, sporocyst, redia, and cercaria. The phylogenetic relationships among the digeneans have been explored relatively recently in both morphological (e.g., Cribb *et al.*, 2001) and molecular (e.g., Olson *et al.*, 2003) contexts, but no higher-level classification scheme is generally accepted. More detailed analysis is required before these relationships can be resolved with any confidence.

There is little doubt that the cestodes are monophyletic. All cestodes lack essentially all elements of the digestive system and exhibit unique extensions of the neodermis called microtriches (**Figure 16**). The Eucestodes are particularly unusual in that their sperm lack mitochondria. The relationships among the cestode orders, and also the circumscription of some orders, remain controversial despite the fact that this issue has received much recent attention (e.g., Waeschenbach *et al.*, 2007). The recent erection and resurrection of five cestode orders (Bothriocephalidea, Cathetocephalidea, Diphyllobothriidea, Litobothriidea and Rhinebothridea) attests to the active state of cestode phylogenetics. The monophyly of the Tetraphyllidea is particularly problematic; the order is almost certainly not monophyletic even with the recent extraction of the Rhinebothriidea.

Host Associations

It is useful to consider host associations in general terms. The tendencies of platyhelminths to live in association with other organisms are summarized on the tree in **Figure 1**. One of the most striking aspects of this mapping is that it becomes apparent that all but six of the major platyhelminth groups (catenulids, macrostomids, haplopharyngids, "lecithoepitheliatans," bothrioplanidans, and kalyptorhynchs) include at least some species that live in association with other organisms. Thus, symbiosis, in its broadest sense, is a widely distributed feature among the platyhelminths. Within the major platyhelminth groups, however, symbiosis varies in its occurrence. Only the neodermatan groups and the temnocephalids consist entirely of obligate symbionts. The dalyelloids and fecampiids are predominantly symbiotic, although a few free-living species are known. The remaining groups (polyclads, proseriatans, triclads, prolecithophorans, and "typhloplanoids") are predominantly free-living, but all of these groups also include at least some species that are symbiotic.

The hosts of almost all of the symbiotic non-neodermatans are invertebrates; molluscs, arthropods, and echinoderms figure prominently in this role. The neodermatans are unlike almost all of the other symbiotic platyhelminths in that they are generally associated with at least one vertebrate host group at some point in their lives. The aspidogastreans are somewhat exceptional in that some species are known only from freshwater clams and snails. However, records of aspidogastreans from the digestive system and its associated organs, in turtles,

elasmobranchs, and teleosts are not uncommon. Although uncharacteristic of the group as a whole, some monogeneans (e.g., gyrodactylids) are found associated with cephalopods, and others with crustaceans that parasitize teleosts or elasmobranchs.

With the exception of the monogeneans, the neodermatan groups are also unique in that their life cycles generally involve more than a single host species. All digeneans possess at least two different hosts in their life cycles. In general, the first (intermediate) host is a mollusc, while the final (definitive) host is a vertebrate. In species possessing life cycles involving more than two hosts, there is one (or sometimes more) additional intermediate (or paratenic) host that is either an invertebrate or a vertebrate depending on the digenean group. In such taxa the host that precedes the vertebrate is generally an invertebrate, often some sort of mollusc or arthropod. The monogeneans are exceptional in this respect as their life cycles involve only a single host.

Symbiotic platyhelminths are found either in or on their hosts. The non-neodermatan groups are often found on, rather than in, their hosts. The exceptions are the fecampiids, "dalyelloids," which are most commonly found inhabiting the coelom or digestive tract of their hosts. Among the neodermatans, the monogeneans are unique in that they are generally found on (i.e., ectoparasitic), rather than in, their hosts whereas the remaining neodermatan groups are most commonly found as endoparasites of their respective hosts.

Medical Importance

The medical and economical importance of the various platyhelminth groups is closely tied to the type and intimacy of the host associations of the groups. Species that use vertebrates as hosts are obviously of much greater concern to humans than those that do not. Thus, the neodermatans are by far the most medically and economically important platyhelminth groups. Space limitations do not permit discussion of the economic consequences of infections with neodermatans, but some of the medically important species are briefly discussed below.

Within the neodermatans only the digeneans and cestodes include species that infect humans. Among the 25 superfamilies of digeneans, human parasites are essentially restricted to four. In the majority of these species it is the adult stage that parasitizes humans. Many of these species are zoonotic; that is, their normal hosts are usually vertebrates other than humans. Humans acquire infections with such species when they unwittingly ingest the metacercarial stage. These zoonotic groups infect a variety of different organs in their human hosts. They include a total of eight species of lung digeneans in the superfamily Gorgoderoidea, five species of liver digeneans in the superfamily Opisthorchioidea, and seven species in the superfamilies Echinostomatoidea, Opisthorchioidea, and Gorgoderoidea that inhabit the digestive tract of their hosts. Finally, human infection with cercariae of species of the superfamily Schistosomatoidea that normally infect birds and aquatic mammals is responsible for an irritating skin condition in humans known as cercarial dermatitis or swimmer's itch.

Only six species of digeneans parasitize humans as their normal final (definitive) hosts. These include one species of liver fluke in the superfamily Opisthorchioidea and five species of blood flukes in the superfamily Schistosomatoidea. The unusual life cycle of the schistosomes requires that humans come into contact with the free-swimming cercariae of these species to acquire an infection. Schistosomes, which cause a disease known as schistosomiasis in humans, are without question the most deadly of the digeneans. Hundreds of millions of people globally are infected with these species. Schistosomes are responsible for the deaths of tens of thousands of people each year.

Species that parasitize humans belong to only two of the 18 orders of tapeworms. The adults of at least four species of diphyllobothriideans (all of which are members of the genus *Diphyllobothrium*) have been reported from the digestive system of humans; evidence suggests that all of these species are zoonotic in humans, as they normally parasitize other fish-eating vertebrates as adults. Plerocercoids of some species of diphyllobothriideans of the genus *Spirometra* are known to parasitize the musculature and subcutaneous tissues of humans, causing a condition known as sparganosis. By far the most pathogenic of the human tapeworms, however, are the cyclophyllideans. Nine species in five genera parasitize humans. These species are known from humans as either larval or adult stages. Larval stages are generally much more pathogenic than adult stages. The hydatid cysts, coeneri, and cysticerci of *Echinococcus*, *Multiceps*, and *Taenia* species, respectively, are arguably the most life-threatening of the human-infecting cestodes. These larval stages often develop in difficult-to-treat extraintestinal sites, such as the brain, or grow extremely large and, in some cases, invasively into one or more organs of the body, making surgical removal of the parasite difficult. Thus, infection with any of these larval stages can be fatal. Infection with an adult tapeworm is generally debilitating rather than life-threatening, because these stages remain in the digestive system and thus are relatively easy to treat. With the exception of *Taenia solium*, it appears that tapeworm infections in humans are also all zoonotic. Infection with adult tapeworms can be prevented by properly cooking food. Infection with larval stages usually involves contact with fecal matter from humans or other animals.

Glossary

AZA Association of Zoos and Aquariums, a North American professional organization.
Ex situ Outside the natural range. Hence, a captive breeding program in Europe for a South American species would be an *ex situ* program. (Conversely, a Chinese program to breed native panda bears in captivity is an *in situ* breeding program because it is within the natural range.)
Exotic animals Animals that have not been domesticated for use by humans in agriculture or as pets; also connotes that the wild animals are from another region of the world.
Founders Animals that were collected from their natural range and that have produced progeny in captivity (and are assumed to be unrelated). Thus, these animals are the founding stocks of the captive population. Also generalized to include animals with wild parents that are collected in order to supplement the genetic diversity of an established captive population.
International Species Information System (ISIS) A central repository for zoo animal records founded in 1973; has also developed the computer programs that most zoos use for keeping their animal records, as well as software used by zoos for studbooks.
Studbooks Also called genealogies, registries, or pedigrees, a database of historic and living animals intended to go beyond passively recording bloodlines and records; typically kept in computer databases that are also useful for actively managing the genetics, demography, and husbandry of captive populations.

Introduction

Zoo is a handy three-letter word, and thus in this article "zoos" will be used in a very general way to include any public or private institutions that house live exotic animals, largely for the purposes of exhibition to the public. Zoos are permanent establishments that are open to the public to provide education, recreation, and cultural enjoyment. Zoos, for purposes of this discussion, are not transient shows such as circuses or petting zoos. Nor are zoos private collections of exotic animals. "Zoos," defined thus, include the facilities that are traditionally considered zoos, such as zoological parks and aquariums, and also many wildlife centers and "bioparks," as well as some insect houses and *ex situ* breeding centers. There are currently over 1200 well-established zoos worldwide.

Zoos reach a vast audience; for example, North American accredited zoos attract more visitors, currently estimated at over 175 million annually, than the major professional sports combined. Worldwide, zoo attendance is estimated at over 600 million visitors (Gusset and Dick, 2011). The best modern zoo exhibits are sublime, invoking in visitors a sense of awe and respect for nature. Zoos are increasingly operated by specialized, professional staff in partnership with government and private interests, with the express goal of conserving wildlife. The main focus of this article is on how zoos are evolving into institutions for wildlife conservation, and also on the art and science of managing biodiversity in zoos.

The Changing Role and Facade of Zoos

Zoos from Ancient to Recent Times

Zoos probably arose as places of spectacle and entertainment shortly after civilization became urbanized. The first recorded zoological collection dates to 2500 BC, when several thousand wild animals are documented in Saqqara, Egypt. Ancient Egyptians kept many wild species for use in religious ceremonies, or perhaps because they hoped to tame them. These ancient animal collections were acquired as tribute gifts or via expeditions that were mounted specifically to collect wildlife.

Zoo collections have sprung up independently on many continents and in many civilizations. For example, Chinese

emperors as far back as 1150 BC had walled animal collections they called "parks of knowledge." When Cortés reached Mexico City in 1519, he witnessed, and then destroyed, the Aztec ruler Montezuma's immense zoo and gardens. Montezuma's zoo was so large that 300 keepers were employed for the aviaries alone, and it even housed malformed humans as part of the collection. Most of the zoological collections of antiquity were imperial and exclusive – symbols of wealth and power. They were menageries in the sense that they were collections of living trophies to be managed.

Collections during Roman times were also for the amusement of citizens. Large numbers of wild animals were used for blood sport and spectacles; holding areas that also allowed public viewing, called *viveria*, were associated with arenas. After the fall of Rome, collections of wildlife were not so common in Europe. During Europe's Middle Ages, imperial menageries once again became more significant. Wild animals were used as diplomatic gestures – as tributes and ceremonial gifts.

The roots of public zoos are somewhat contemporaneous with the emergence of Europe's great cities. London gained a zoo, of sorts, in 1252 when Henry III transferred his menagerie to the Tower of London; London's citizens were pressed to support the menagerie, and in turn the public could view some of the animals, such as a polar bear and an elephant. Urban menageries, under the sponsorship of merchants and other citizens, began to emerge, first in Frankfurt in the late 1300s, then in the 1500s at The Hague and in Augsburg.

The rising profile of zoos can be traced to the Renaissance, when trade and exploration brought more animals into Europe. Colonial officers in far-flung empires served as conduits for animal requests. Public interest was most piqued by the wildlife of Africa and the Far East. The first zoological garden, which combined displays of plants and animals, was established in Versailles by Louis XIV in 1665; in 1794 this collection became a division of Paris' natural history museum, creating a formal link to zoological research that was later emulated by many other zoos and museums. The first "modern" zoo that survives to this day is probably the Schönbrunn Zoo in Vienna, originally established as a private collection in the 1770s, but to which the public were intermittently admitted.

The nineteenth century has been hailed as the century of science and the golden age of museums. This century witnessed an explosive increase in the numbers of zoos and museums. Scientific societies sprang up, including zoological societies. Zoological research was nominally based in nineteenth-century zoos, but the inquiry was mostly limited to collecting and classifying. Local governments tended to operate zoos of this era with the aim of providing recreation and edification for the increasingly better-educated citizenry that arose with the Industrial Revolution. Zoos were sources of civic pride, and they competed to exhibit as many kinds of animals as possible. The rise of print media made it possible for civic leaders to compare collections more readily with rival zoos. Natural social groupings were largely ignored, and frequently solitary animals were displayed. Generally species were grouped to correspond with scientific classification, for instance, into bird, reptile, or carnivore houses. These animal collections were viewed as analogous to collections of art, and even the zoo architecture of the period came to be considered art.

An innovation at the beginning of the twentieth century was habitat exhibits, as pioneered by Carl Hagenbeck at Tierpark, outside Hamburg, Germany. In these zoos of living panoramas, it became increasingly common to display animals along geographic lines rather than strictly taxonomic ones. Habitat exhibits were well suited to zoo designs that intended to teach ecological principles, and thus led to the display of animals in more natural social groupings. Eventually mixed-species exhibits became more common, and these conglomerations might even be grouped by ecological biomes such as "polar zone" or "tropical zone," rather than along strictly geographical or taxonomic lines.

Later in the twentieth century, world culture became increasingly electronic and graphic. Zoos found themselves in competition with wildlife film documentaries. No longer would the animal displayed in a sterile cage suffice for an increasingly sophisticated audience. "Immersion" exhibits became the ideal for most new zoo development. Immersion exhibits are ones that seek to make visitors feel that they are in the habitat with the animals. This may be accomplished by incorporating the same details of rocks, logs, or plants into both the animal and the public space, using these same details to hide any cage elements, and also by special effects such as mist machines and animal call background soundtracks that help create an illusion. Barriers to separate animals and people may be relatively invisible (e.g., glass) or carefully placed so they are unobtrusive. Special feeders and techniques of animal management may be used to encourage animals to be active and visible – for example, hidden heating or cooling pads for animals to lounge on, depending on season, or feeders that intermittently spray out small amounts of food near a viewing station to encourage visible foraging behavior. Zoos often try to craft the visitor space so that visitors do not see other visitors while observing the animals. In many instances, the designers' intent is to evoke an almost religious experience of awe and respect for nature, much as the grand cathedrals did in early eras.

Rise of the Zoo Conservation Ethic

Zoos, as we have seen, arose as places of spectacle, not as conservation organizations. But many modern zoos have chosen wildlife conservation as their primary mission. The conservation ethic has developed in zoos over the past century in parallel with the nonzoo world, and in many cases one can point to zoos as the places that incubated the people and ideas that have led to important conservation developments (Norton *et al.*, 1995). The National Zoo in the United States, founded in 1887, is considered to be the first zoo created to preserve endangered species.

Conservation of wildlife and wildlife habitat has become the major goal of most of the prominent zoos and zoo professional organizations (IUDZG/CBSG (IUCN/SSC), 1993). Although altruism is part of the reason for the shift, compelling utilitarian reasons also drive these lofty goals. As humanity expands and wild places contract, exotic animals are getting scarcer, thereby reinforcing the zoo conservation mission while presenting the reality that zoos must become net producers of wildlife if their animal exhibits are to remain vibrant, inspirational, and of a multifaceted significance to

conservation. As regulators seek to simultaneously protect their natural resources and their agricultural sectors, governments make it ever more difficult to import and export wildlife. Wild animals may carry diseases that will harm livestock and perhaps even spread to the human populace; increasing understanding of disease has led to import restrictions or quarantines. For example, the bird-importing era, at least in the United States, slowed markedly in the early 1970s, when quarantine laws were enacted to guard against Newcastle's disease. In the 1990s the Wild Bird Trade Act was passed in the United States to restrict importation of any birds protected by CITES, the Convention on International Trade in Endangered Species of Wild Fauna and Flora. Most professional animal dealers have gone out of business due to the increasing restrictions, and zoos collectively have supported these regulations as part of their conservation mission.

Simultaneously, zoos have needed to import fewer animals because they became more proficient at keeping and breeding wildlife. Zoo keeping is a complicated art and science, and zoo keepers and managers have found it useful to pool their knowledge. Furthermore, single zoos are rather like islands from a population biology point of view, in that they are not big enough to sustain viable populations. So cooperative breeding programs for animals have become key, while cheap, fast transport, usually by air, makes it feasible for distant zoos to exchange breeding stocks. In many regions of the world, the leading zoos and their staff now belong to professional organizations. There are also world zoo organizations that help link the regions. These organizations have codes of ethics and accreditation (certification) programs. For example, North America's American Zoo and Aquarium Association (now renamed the Association of Zoos and Aquariums or AZA) was founded in 1924 and currently includes 223 accredited institutional members (this is about one-tenth of the number of animal exhibitors that are licensed with the US government).

Public support is yet another motive for many zoos to become conservation organizations. Zoos experience challenges in the competition for public funding. Modern zoos are costly, with expensive professional staffs, sophisticated veterinary medicine facilities, and a public that demands complex, educational, and artistic exhibits (Conway, 1986). Municipal governments are increasingly burdened by social programs and other competing demands for funds and now only fund a fraction of zoo operations compared to earlier times (on average 21% of the zoo budget in North America). But while the funding situation is tough in the richer nations, it is often quite desperate in poorer regions of the world. Most zoo-based conservation is being done by the "haves" whereas much of the need for conservation and access to endangered species is in the "have-not," largely tropically located zoos of the world.

There is enormous public support for environmental causes and grants available for conservation programs. Despite a vocal minority of critics who question the ethics of keeping animals in zoos, zoos are maintaining enormous popularity as they further refine their role as advocates of, and players in, wildlife conservation (Falk *et al.*, 2007). Zoos have often contributed significantly to the economies of their regions. AZA figures indicate $15 billion in annual economic activity among the AZA-accredited zoos and the support of 142,000 jobs. For instance, the Chicago Zoological Society estimates that their Brookfield Zoo generates $150 million to the Chicago area whereas the four zoos and aquariums run by the Wildlife Conservation Society in New York City are worth approximately $350 million to New York.

Animal Welfare in Zoos

Advocates for animals are becoming increasingly strident, even to the extent of using terrorist tactics. Their ire is more typically directed against laboratories that use animals, but zoos also have come under fire. Some animal rights extremists have expressed a goal of putting zoos out of existence. Extreme though these views may be, they signal a shift in public attitudes toward animal welfare. Many people now consider animals as fellow creatures with needs and feelings that should be respected. Zoos that have not become attuned to perceptions of animal welfare have often experienced an erosion of public support, often regained by a renaissance of rebuilding on existing or new sites and hiring some of the best professionals in the business. Some of the poorer, old-fashioned zoos have closed.

These animal advocates often confuse animal rights with animal welfare, and their anthropomorphic ideas about what animals need are often at odds with what is best for animals. For example, well-meaning protestors tried to prevent the transfer of a gorilla named Timmy, who had never procreated, to a zoo in New York that had considerable success in breeding gorillas as well as many potential fertile mates for Timmy. The protestors did not want Timmy to be separated from his current, infertile female partner. However, in nature gorillas do not form monogamous bonds and they do transfer from one social group to another. Eventually, after a court found the transferring and recipient zoos to be in total compliance with both the Endangered Species Act and the Animal Welfare Act, Timmy was moved, formed bonds with new females, and has begotten numerous offspring.

A related problem that we shall return to in the section Keeping Biodiversity is the problem of limited space in zoos. Thus, breeding unwanted, "surplus" animals is a problem for zoos because surplus animals inhabit valuable space. Some zoos take the apparently logical stance, from a utilitarian animal management vantage, of culling their surplus stocks or selling them to the private collectors. In private hands, some animals have ended up on game ranches where they are shot for sport. This has caused major public relations imbroglios, as a result of which zoos have had to examine their ethical policies and restrict their animal trade to accredited zoos. Zoos have developed contraceptive and husbandry techniques to prevent unplanned breeding, and they have developed scientific breeding plans to keep population demographics aligned with available space. Furthermore, there has been a trend of exchanging animals without fees as they become increasingly priceless.

Improved contraception for animals is just one example of how health care for exotic animals is becoming increasingly sophisticated. Improved veterinary care deserves much of the credit for allowing zoos to shift from relatively sterile concrete and steel cages to more natural housing, which is often,

literally, dirty (as the substrate is frequently dirt or other organic matter). Most zoos now have their own veterinarians and veterinary hospitals. Some even have pathologists, endocrinologists, and nutritionists providing preventive care, better drugs, and diagnostics. The understanding of wild animals' nutritional needs is advancing rapidly, and there are now numerous commercial brands of food for exotic animals, such as "Flamingo Fare." Nutritionists are even improving on fish diets (which are expensive and become depleted of certain vitamins during shipping and storage) for animals such as penguins and sea lions by devising a gelled, artificial fish in a fish shape. Most zoos have "browse" programs to grow and harvest fresh plant foods for their denizens.

There are numerous technical periodicals, books, and other publications related to zoo husbandry, including *Zoo Biology*, the zoo profession's peer-reviewed science journal, *International Zoo News*, the *International Zoo Yearbook*, *The Shape of Enrichment*, and *The Dodo*. As a testament to the improving welfare of zoo animals, zoos are now recording many longevity records, and zoo animals frequently senesce and die of old age – an almost unheard of occurrence in nature. As zoos have become more successful at keeping exotic animals alive and meeting their physical needs, the attention of zoo biologists has begun to shift toward behavior.

Zoos have also added applied psychology to their toolkits. They now must reassure their public that animals are not distressed but are potentially "happy." New techniques are being developed to stimulate zoo animals, reduce psychological stress, and elicit cooperation rather than coerce desired behaviors (Shepperdson *et al.*, 1998; Watters and Wielebnowski, 2009). Some zoos train animals to perform in shows, which is not a new phenomenon. But modern shows demonstrate natural behaviors to the public and keep the performing animals occupied, rather than emphasizing cute tricks or an animal's fierce nature. These new techniques range from behavior management and operant conditioning to environmental enrichment. Behavioral techniques aim to banish boredom, eliminate stereotypic tics, and otherwise encourage behavioral patterns that approximate those of animals in nature. For example, the Chicago Zoological Society has made a major commitment to behavioral science as it applies to zoo animal management through their Center for the Science of Animal Welfare (see http://www.brookfieldzoo.org/czs/Animal-Care/Center-for-Science-and-Animal-Welfare).

Emerging Trends

Zoos, as we have seen, have evolved from imperial menageries to the modern habitat and immersion exhibits that feature animals in more natural settings and social groupings. In the twenty-first century, we expect this trend toward more ecological themes to continue, with more zoos featuring animals in diverse, mixed-species exhibits. Zoos that predominantly have these diversity-designed exhibits have been given the moniker "biopark," or "biodome." This sort of zoo may feature botanical collections housed with terrestrial and aquatic vertebrates and invertebrates. There is a considerable art in developing these mixed-species exhibits, because zoos must ensure that cohoused animals do not decimate the foliage or each other. Animals that do wreak havoc with plants or other animals are either excluded from the biopark or managed separately, although their exhibit boundaries may be crafted carefully so that this is not obvious. Some zoos are extending this idea to focus on the ecology of a certain region using both zoo exhibits and more museum-like exhibits; typically the focus may be the region in which they are located – for example, the "living desert museums" in the American southwest near Tucson, Arizona and Palm Springs, California.

Also emerging in the twenty-first century seems to be a new trend, which we shall call "conservation edu-tainment." These thematic exhibits have a storyline to which visitors may be introduced, sometimes through videos or costumed actors, as they wait to enter the exhibit. This visit may even include an amusement-style ride; for example, Sea World visitors to the polar region exhibit experienced a "tundra buggy" simulated ride before viewing polar bears and other creatures. Some call this the "Disneyfication" of zoos, after a zoo, "Disney's Animal Kingdom," that the Walt Disney Company opened in Florida in the late 1990s; one feature is a drive-through, safari-style bus ride, where the storyline is that visitors are joining a patrol to catch poachers.

The actual educational value of these new-style zoo exhibits is debatable, and a still greater unknown is whether the lessons learned by visitors will translate into conservation actions. Conservation education, zoos have argued, is one of their major contributions, one that is becoming increasingly important as citizens become further distanced from nature. Zoos are trying to justify these claims, and also to do a better job of conservation education. Thus, zoos are beginning to scrutinize their exhibits and programs using evaluation techniques. Evaluation methods, including surveys, interviews, or observation of visitors, are sometimes employed during the design phase to improve the message before expensive construction begins. They may also be used at other times to help fine-tune exhibits or otherwise inform about how the zoo is working or what the audience is like. The science of evaluation is rapidly developing in zoos and museums, and it will probably become an increasingly important part of zoo planning for quantifiable conservation outcomes and mission accomplishment (Falk *et al.*, 2007).

As the world becomes more wired to the Internet, zoos are following suit. Many zoos now have websites where visitors can find information about the zoo, and many also use social networking media. Some zoo databases, including the vast International Species Information Service (ISIS) registry of zoo animals, are now available at Internet websites. The newly launched Zoo Information Management System (ZIMS), aims to increase information sharing about collections for better animal management and population sustainability. Some zoos are incorporating electronic media into their educational efforts, either integrated with exhibit graphics or separately. Cooperative breeding plans, and the data needed to manage them, will increasingly be shared via electronic means. And some website programs (for example, one for trumpeter swans) allow school children and others to dynamically follow the movements of reintroduced animals via satellite tracking. Virtual zoos will not keep real animals, which is the primary business of zoos, so zoos will probably continue to find ways to use the Internet that enhance rather than radically change what they do.

As the supply of wild-born founders dwindles, and more amenities are expected for the animals in hand, zoos are abandoning the one-of-each-kind collecting approach. Within-zoo species diversity is decreasing in order to make room for zoos to manage larger, more natural social groups and to house a breeding nucleus of at least several pairs and their young offspring of nonsocial species (Gibbons *et al.*, 1995). Many zoos are trying to allocate a proportion of their animal space for off-exhibit breeding efforts, and some are operating special facilities devoted to breeding of endangered species – mostly *ex situ* but also some *in situ*. Many zoos are developing specializations, concentrating their efforts on the specific groups of animals that they can keep best and exhibit most dramatically. Zoo workers are also becoming more specialized, both along taxonomic lines and also professionally into fields such as educators, veterinarians, nutritionists, population biologists, behaviorists, life-support system operators, pathologists, and horticulturists. With the increasing need for cooperation, more formal committees and other structures are developing through the professional organizations.

Choosing Animals to Promote Biodiversity Conservation

Space, the Final Limit

Modern zoos are expensive to build and upgrade. In North America alone, zoos spend millions of dollars per year on capital or physical improvements, with much larger expenditures for major new exhibits or zoo facilities. A major exhibit can cost in the tens of millions of dollars and typically takes at least 3 years to plan and build. Maintaining a zoo and its animals is also very expensive. Therefore, there are practical limits to how many zoos can be supported and thus to how many animals can be maintained by zoos (Conway, 1986). For example, the number of animals that are presently kept in the 223 accredited zoos of North America is approximately 870,000 from among 6000 species.

Thus, conservation-oriented zoos choose their inhabitants with care in order to maximize the biodiversity that they preserve in their finite space. A biodiversity trade-off must be made between the number of species that are maintained by zoos versus the genetic diversity or size of the captive populations that are maintained. Zoo planners have to think long-term because they are trying to maintain viable populations for decades or centuries. In many cases, zoo populations are, essentially, closed gene pools because it is difficult or impossible to acquire new lineages or wild-caught "founders." Extinction in nature is the most obvious cause for a closed captive population, and zoos work with several "extinct" species such as the Prezwalski's horse. But species that are extant in nature can also be effectively isolated in zoos by government import or export regulations, concerns about disease transmission, rarity in nature, political issues, or the extreme difficulty and expense of collecting some species. In most cases zoo planners also try to "save all the pieces" by managing their populations for genetic variability. Genetic variability is an achievable objective since anything approaching natural selection is by definition impossible while the animals are under human care. Arguably, this is a prudent and responsible strategy should the animals be needed someday for restocking wild habitats. Habitats are also changing, so the theoretically successful genetic profile of the past might not be the same in the future. By breeding for variability, i.e., retaining as much of variability as was present in the original wild-caught founders as possible, the potential for readaptation to old or new habitats is maximized.

Hence, zoo population plans usually strive to breed animals better than would be done randomly without a scientific framework, and they often try to do this by maintaining small, well-managed populations that are projected to be genetically and demographically viable well into the future. This usually requires a captive population of several hundred animals. In this effort, attention must often be paid to picking the right unit for conservation, or the evolutionarily significant unit. Zoos have funded a considerable amount of applied molecular genetic research in order to determine subspecies and species characteristics, thereby avoiding the possibility of breeding animals that are similar-looking but are in fact different species. The converse is just as problematic when members of the same species are perceived as distinct and maintained separately, taking up valuable space and/or compromising the viability of both populations with suboptimal numbers.

Metamanagement of Zoo Biodiversity

Each zoo is an island too small to do much conservation breeding on its own. To facilitate cooperation, organized conservation programs involving captive animals are beginning to develop around the world through regional zoo professional associations. Most of the labor that goes into these programs is pro bono or volunteer. Much of the work is accomplished through workshop meetings and via committee, at considerable personal and institutional expense.

The basic unit of these programs is the studbook, which is the database of historic and living animals in a particular captive population. Studbooks are usually maintained through the efforts of one "studbook keeper." Populations that are monitored with studbooks can be managed through regional or even global captive breeding plans, usually overseen by a committee, which specifies where each animal should be and whether it should be bred.

To prioritize how much captive space various populations should be allocated, zoo specialist groups for each kind of animal have formed, and are known as "taxon (for taxonomic) advisory groups." Taxon advisory groups typically work closely with the appropriate taxonomic and scientific specialist groups of the World Conservation Union (IUCN), as well as with scientific advisors. Regional taxon advisory groups tend to develop priorities that are complementary to those in other areas; for example, Europe may choose to allocate space to breed a different species of penguin than North America. Taxon advisory group priorities are formalized into "regional collection plans," which ideally include a justification for including or excluding each species or subspecies in the taxonomic group, as well as setting a target population size for each managed population. These plans may also specify areas where research is needed, or where field conservation should

be a priority. Tools are being developed to facilitate regional planning, including metacollection software that has been developed by Australian zoos.

The representation of biodiversity in zoos is biased toward animals that are furry, large, brightly colored, or otherwise captivating for people. In general, the more closely related to humans, the greater the representation. So most kinds of primates are kept in zoos and managed through cooperative programs, whereas only a fraction of rodents or bats are represented. Similarly, most kinds of flamingos can be found in captivity, whereas only a fraction of the small perching birds are kept. A smaller proportion of birds are maintained in organized programs than mammals, but only a fraction of the scaly creatures (fish, reptile, and amphibian) are kept. Very few invertebrates are represented in captivity, but this seems to be changing as butterfly exhibits and insect displays are gaining in popularity. Invertebrate husbandry is relatively primitive for both aquatic and terrestrial species; the public generally considers the collection of wild invertebrates acceptable, so there has been less pressure to develop husbandry techniques. The situation for fish, and most other nonmammalian aquarium denizens, is similar to that of invertebrates.

Institutional Planning

Zoos as individual institutions are also becoming very mission-oriented. Many zoos have developed mission statements and master plans for growth and development. These plans provide the overall organization of the zoo exhibits and the visitor traffic patterns as well as locations of facilities for merchandise, refreshments, and bathrooms. (Bathroom location is amazingly important for a positive visitor experience!) Master plans usually designate the kind of educational messages the zoo will try to convey and the themes of the exhibits. They may be informed by practical considerations of what animals and plants will do best in the zoo, and these may be based on local climate or the experience and expertise of the zoo's staff.

Within the context of the master plan, zoo planners, typically curators, will develop an animal collection plan. Ideally, curators will develop these plans after studying the regional collection plans that have been developed for metamanagement of zoo collections. This collection plan will usually list each species that the zoo keeps or wishes to obtain, along with a justification for what the species will contribute to the zoo and to conservation of the species. The plan should say how many individuals there are of each sex, and how many are desired. The plan will specify where these animals will be housed. If the species is managed by a cooperative breeding plan, then the institutional collection plan should include the recommendations for which animals are to be bred and which are not. If not part of a cooperative plan, the curators should have a breeding and possibly a research plan of their own. Institutional collection plans usually need to be updated annually.

Keeping Biodiversity

Zoo Animal Records Keeping

Basic to managing animals and improving husbandry is keeping track of the inventory and gathering data. The memory of zoo staff is no longer sufficient to keep these records, as animals live longer and breed better, the government expects more information, and both animals and keepers are more mobile. Zoos are tracking an ever-increasing amount of information about their animals. Each animal in the inventory, current and historic, is accessioned, which means it is assigned a unique identification number. The animal also must be physically identifiable, so most are tagged or marked; this can be done with traditional bands and tags or with more high-tech injectable microchips. Records are kept for diverse variables, including characteristics that allow an animal to be individually identified, dates of birth and death and other life-stage transitions, sex, parents, offspring, current and previous locations, health notes, cage mates, previous owners, physical parameters such as measurements, species and subspecies, and behavioral observations. Zoos are standardizing their data collection and records so that all this information can be pooled.

Keeping these records has turned into a specialty of its own, and the keepers of the data are usually called "registrars." Registrars may also be responsible for some of the government permits and paperwork associated with modern zoo keeping. These data are generally organized into a computer database. The most widely used program is Animal Records Keeping System (ARKS) that was developed by ISIS in 1985. ARKS generates a variety of standard reports. In addition, ARKS is useful for looking up simple questions about individual animals (for example, potential exposure to disease) as well as for mining the data to seek trends or clues to larger questions.

Most zoos send their ARKS data to ISIS at regular intervals so that it is backed up and also so that parts of the central database can be combined to create an international inventory. This international data is useful for various other purposes such as cooperative breeding programs, scientific research, or for governmental authorities. A weakness of ARKS is its limited ability to manage data for group-living or colonial species. Thus ARKS is of little use for managing animals such as schooling fish, many invertebrates, colony-nesting birds, or other animals that are kept in groups with multiple adult males and females. Similarly, animals that breed in relatively large enclosures (such as ducks in large ponds or fish in large tanks) are difficult to keep track of with individual records. Because of this weakness, animal records for aquaria and invertebrate collections are not standardized. As genetic identification becomes less expensive and more available, the possibility for tracking the genetics and demographics of large colony collections becomes much more feasible.

Zoo Population Management Strategies

Zoos have historically made much of their "babies," as births were and still are exciting events of much interest to the public. Prior to the development of management plans, rare breeding successes for a particular species tended to be replicated and replicated again. Then zoo curators would notice that there was a surplus of the species and they could no longer find good homes for the babies. Thus, all zoos would stop breeding the now-abundant species all at the same time. Some years later, as the stocks of the animal were aging and

starting to die off, there would again be room and demand for babies, and curators would try to resume breeding. But all too often, it would be too late for the aging stocks and the captive population would be lost.

To prevent these boom-and-bust breeding cycles, beginning with the launch of the Species Survival Plan (SSP) concept in 1980, zoo biologists have developed population management strategies and tools (Gibbons *et al.*, 1995). Key to zoo population management is gathering information about all the animals in the managed, captive population (the managed population often is not identical to the captive population because nonaccredited zoos and private collections are often not part of the cooperative program). The population data are kept in studbooks, which contain genealogical information as well as demographic information. As in zoo records keeping, ISIS distributes the most popular database for studbooks, a program called SPARKS, which stands for Single Population Analysis and Records Keeping System. The studbook programs integrate with computer software such as PM 2000, lately updated as PMx (PM = Population Management), that performs much of the demographic and genetic analyses that are essential to zoo population management.

Two principal kinds of conservation breeding programs are the current standards. The first is a program that participants essentially sign a contract to join, and agree to abide by the decisions of an elected committee. This type of program was first introduced in the United States, and was named the SSP; nearly identical programs are known by other names in other regions of the world. The second kind of program is a less intensive one, in which recommendations are issued but individual zoos elect whether or not to cooperate. In North America this second kind of program is known as a Population Management Plan (PMP). These two kinds of programs follow similar population management strategies but differ more in the intensity and politics of the actual management. The SSP also has conservation, research, and education components, whereas the PMP is strictly for population management. Recently, it became mandatory for AZA-accredited zoos holding SSP species to participate fully in the SSP-managed programs.

Planning for conservation breeding programs generally begins by determining the purpose of the program. Will animals from the population eventually be returned to the wild, or will the primary purpose of the population be for exhibition in zoos? The managers should decide what the appropriate population is for management purposes – for example, whether to limit the management to a subset of the animals that are known to derive from founders of the same subspecies, while excluding those that are of more uncertain ancestry. Once these decisions are made, demographic and genetic goals are set. Genetic and demographic analyses are done using the studbook data and specially designed software. The analyses are used to estimate parameters, which are needed for the long-range population forecasts that are used to guide the goals. Goal setting is done with the help of analytical tools that consider the number of founders (amount of genetic diversity that was likely to be captured), the effective population size N_e, the current population size, the rate of population growth, the number of years since the program was founded, and the generation time. Typically, conservation breeding programs aim to preserve greater than 90% of the original diversity for at least 100 years. Sometimes it becomes apparent that demographic intervention is needed, perhaps to increase the population growth rate, lengthen the generation time, or increase the number of spaces available so that the population can grow. At other times managers realize that more founders must be imported, if possible from zoos in another region of the world, but sometimes from nature.

As an aside, zoos have sustained much criticism from conservationists for taking animals from the wild for exhibition, including charges that this has led to the depletion of wild stocks. Zoos rebut that the number of animals they take are trivial compared with animals that die through habitat loss, hunting, or other human activities. Good captive management reduces the number of founders, or wild-born breeding stock, needed for long-term population viability. Theoretically, the acceptable number of founders is 12–25 individuals picked at random from a wild population (25 being ideal since each additional founder beyond 25 is unlikely to possess genes not already present in the 25). However, many captive populations start with only a fraction of this number. Even with good management, new founders may need to be added, since not all founders will produce the ideal number of offspring. Founders should be collected with minimal impact on the wild population. The way that this is best accomplished depends on the natural history of the species and the specifics of the program. For example, one low-impact approach to collecting founders is to salvage orphaned or injured nonreleasable wild animals; this opportunistic approach has the disadvantage that it may be slow and that disabled wildlife can constitute poor breeding stock. In extreme cases, such as those of the California condor and black-footed ferret, all of the remaining wild individuals were brought into captivity at the point it was calculated that the wild population was on a trajectory to zero. In both cases, this proved to be the salavation of the entire species. Descendants of these last remaining wild specimens became the ancestors of captive-born animals used to reestablish several new wild populations in the species' historic range.

Once the goals of the population are determined, and plans are made to redress problems such as too few founders, a detailed conservation breeding plan is developed. These plans give a recommendation for each animal in the managed population, which will include whether the animal should be moved, if it should be bred, which animal it should be paired with, and whether any special actions are needed, such as fertility testing.

Scientific principles are given a heavy weight in the planning. Zoo biologists tend to start with demography, using a Leslie matrix approach that incorporates both current and historic data. The demographic software tools were developed at the National Zoological Park by Jon Ballou and Laurie Bingaman-Lackey. Demographic data sets for zoos are often small, but contain highly detailed information compared to wild populations. Therefore zoo demographic estimates are often very crude and may require considerable tweaking. Early in the analysis, zoo biologists look at the population's age structure and sex ratio. If these are skewed, efforts may be needed to create a better demographic balance. The next

consideration is rates of fertility and infant and adult mortality; these estimates are used to project the number of breeding pairs that will be required in order to end up with the desired number of births that will balance deaths and also generate the recommended population growth or shrinkage.

"Genetic representation" of individual animals is the primary variable considered in deciding the animal-by-animal breeding priorities, except that aging, genetically underrepresented animals with only a few breeding years left may be given special breeding priority. Genetic algorithms, largely developed by the Chicago Zoological Society's Robert Lacy, use pedigree-based genetic simulations to assess the genetics of each animal and potential pairing in the population. Managers attempt to simultaneously maximize three parameters when recommending breeding matches: (1) good matches will improve the genetic diversity of the population (i.e., by increasing underrepresented lineages), (2) good matches will attempt to balance the genetic value of male and female, and (3) good matches will avoid inbreeding with close relatives. Balancing the genetic value, which is done by looking at a parameter called mean kinship, or the effective number of close kin, is important because it breeds big families with other big ones and little families with other little ones. New ways of visualizing mean kinship are now being used in PMx so that mismatching of animals with different mean kinship values becomes less important. This is especially useful in managing polygynous species where other difficulties can emerge if genetic management trumps social management.

Although the science of conservation breeding has advanced considerably, practical considerations also must enter into planning. Wild animal keeping in practice is a complex art, and it would be foolish to ignore details such as the distance of a proposed transfer and behavioral and physiological observations. For example, there is no point in recommending a pairing of two gorillas that are incompatible. Similarly, if an animal has not bred after many attempts at several zoos, there may be a physiological problem, or perhaps managers have not yet tried the right trick.

Group-breeding species are a special challenge to zoo population biologists, as they are for zoo animal records keepers. The methods outlined above work less optimally for populations in which a significant proportion of the pedigree is unknown, and also when managers cannot control which individuals mate with which, as is generally the case with group-breeding animals. An approach that is sometimes used is to completely ignore the pedigree and manage the species as a subdivided population, with occasional transfers of animals between demes or subpopulations. But the pedigree-free approach often throws out large amounts of information about a population and results in overly conservative management that will require larger populations than might otherwise be needed. Similarly, species whose life history is more size-dependent than age-dependent are not well served by current methods, and may be better managed using stage-based population management. As zoos move beyond management of animals with relatively simple breeding biology, such as tigers, and tackle species with more complex life histories, new population approaches will be needed. Similarly, as the "brave new world" of reproductive technology develops, frozen zoos will need to become integrated into population planning.

Frozen Zoos and Other High-Tech Solutions

An alluring prospect is that someday we may be able to preserve biodiversity in bottles on a warehouse shelf. Another enticing prospect is the use of reproductive technology to propagate animals that have not reproduced naturally. New technologies are making these prospects possible in some cases.

"Assisted reproduction" is a catchall phrase for a variety of veterinary or endocrine interventions used to promote breeding (Gibbons *et al.*, 1995). Artificial insemination, using fresh or frozen sperm, has been in use for many years in the domestic livestock industry and also for some zoo animals. The techniques can be readily adapted to zoo animals if there is a closely related domestic model in which the technique has been developed; for example, rare species of cows can benefit from research with domestic cows. Zoos have also employed other techniques, such as *in vitro* fertilization with harvested eggs, or embryo transfer both within and between species. The idea of growing a rare species in the womb of a common one is appealing, and has been achieved in some instances.

"Frozen zoos" are being developed by several zoos. In these superchilled repositories, sperm, eggs, and embryos are committed to long-term storage. Now that cloning is also a real possibility, frozen zoos of living cell lines are also being developed (Ryder and Bernirschke, 1997). Saving biodiversity in freezers is tantalizing, but there are many limitations to this approach and hurdles to be overcome.

Assisted reproductive techniques are difficult and costly to adapt to animals that do not have a closely related model, and also for those with complex reproductive physiology, for example, animals with induced ovulation. By and large, the techniques for animals with shelled eggs have been limited to artificial insemination. We cannot, as of yet, grow embryos in a test tube, so those derived from a frozen zoo must be grown in a real womb (or egg). This means a real population of surrogates will be needed to mother the frozen zoo, although in some cases these surrogate mothers can be of a different species. Surrogate mothers may produce animals with species-inappropriate behaviors and possibly even a hybrid phenotype.

Frozen zoos will not preserve learned animal behaviors (culture), and they will not eliminate the need to keep real populations. Frozen zoos, cloning techniques, and the like, as San Diego's Oliver Ryder predicts, will probably become powerful adjuncts to the management of populations. So far, genetic and demographic models for managing zoo populations have not factored in frozen resources, but some day they probably will. This will allow managers to keep smaller numbers of living animals. In addition, relative to the transfer of whole animals, the transfer of sperm, eggs, and embryos between wild and captive populations can be done with far less risk of cotransferring disease-causing pathogens. Thus, these techniques may be highly useful in importing new gene lines into small populations, both wild and captive.

Supporting Diversity in Nature

The Ark Paradigm

Enamored, perhaps, with their newfound ability to breed and manage exotic animals, zoos and their commentators were for

a time fixated on the "ark" paradigm of conservation. That is, like the biblical Noah, they talked about saving species in captivity until sometime in the future when the flood of human population shall recede and there will again be the space, and also the will, to restore Nature. Zoos have actually had some success saving species this way. The list of species that have been rescued from extinction by taking refuge for some time in zoos is ever-growing and includes black-footed ferret, California condor, European bison, Mongolian wild horse, Arabian oryx, Partula snails, and Guam rails. However, some species have become extinct during their captive sojourn and no opportunity has arisen to restore some others – for example, several bird species of Hawaii. We are seeing that restoration of a fauna may be only a remote possibility and the utility of reintroduction overstated in some ways. Where species have been rescued by breeding and reintroduction techniques, it is nothing short of miraculous and remains a model worth pursuing and perfecting.

The Post-Ark Paradigm

Maintenance of captive stocks has several functions, but the singular purpose is not, as it is popularly misperceived, for future reintroduction efforts. Zoos may indeed rescue individual animals and sequester them in the safety of captivity. As zoo professionals look beyond the ark, they are developing many other ways to contribute to the conservation of exotic animals.

Exciting, educational exhibits are potentially zoos' preeminent contribution to conserving animals and their habitats. Worldwide, zoos are estimated to attract over 600 million visitors annually. The majority of these visitors live in urban areas and otherwise have little contact with wildlife. Zoos are beginning to study and develop approaches for mobilizing visitors for conservation through innovative exhibit and educational programs. North America's accredited zoos report that each year 12 million students visit and enjoy onsite education programs, and in addition 85,000 teachers profit from teacher training. Some zoos are even developing "museum schools" in which a zoo or museum actually serves as an alternative school for a small number of students who typically combine rigorous college preparatory curricula with hands-on or applied learning in the zoo setting (more information about museum schools can be found at http://www.astc.org). Zoo-based conservation education programs need not end at the exit gates. Zoo educators and graphic artists can also develop conservation curricula that can be used in other parts of the world, including the native range of some endangered species. There is a remarkable dearth of educational materials about most endangered species within their native ranges, and any effort that zoos can make to redress this problem will be most helpful. Zoos may also need to develop curricula that more directly address the biodiversity crisis, and they may need to reach out more effectively to decision makers (politicians) and leaders of commerce.

Zoos can serve as refuges for displaced, injured, or confiscated wildlife. Thus, zoos help wildlife authorities enforce regulations by providing homes for seized wildlife. In addition, many zoos maintain patches of artificial or natural habitats for native wildlife and can provide significant breeding refuges for some birds and butterflies, and for fish and small animals that need relatively little space for a viable population. The Amphibian Ark, an international program (see http://www.amphibianark.org/), now addresses the amphibian crisis by engaging zoos in field research and conservation as well as inexpensive captive propagation programs.

Zoos sponsor significant basic research, often studies that would be difficult or impossible to accomplish with animals in the wild. Furthermore, zoos invest a considerable amount of money in research; for example, accredited zoos in North America spent $51 million on scientific research in 1998. While developing technology and methodology for captive animals under relatively controlled conditions, zoos create expertise that is useful *in situ* – for example, guidelines for medication dosages.

Direct financial support of field conservation is another way that zoos are helping preserve biodiversity (Gusset and Dick, 2011). Since 2006, accredited North American zoos have been involved in more than 3700 conservation projects in 100 countries, spending approximately $90,000,000. Another form of *in situ* conservation funding is for zoos in the wealthier nations to help improve the conservation impact of zoos in less-developed nations. Many zoos also sponsor member tours to see wildlife in nature, and they try to make arrangements that will have a positive impact on conservation.

The Ark Revisited

Human populations are still increasing and wildlife will continue to disappear. More direct conservation measures will be needed from all zoos. Zoos will be called on to provide refuge for more species as the wild populations dwindle. Shrinking wild populations in postage-stamp parks may need to be managed more like zoo populations, with infusions of unrelated lineages, potentially from zoo stocks. Intensive, joint, metapopulation management of *in situ* and *ex situ* wild animals will require both scientific and political innovation. Zoos may indeed help to save some wildlife from the flood of humanity, but they probably will not be acting as closed vessels. Rather, expect to see zoo-based conservation continue to become increasingly dynamic and interactive.

GLOSSARY

Abiotic Referring to the non-living components of an ecosystem; i.e., the chemical and physical environment.
Ablation A direct transfer of water molecules from ice crystals to the vapor phase, without transition through the liquid phase.
Abundance 1. The number of individuals of a given species in a region, area, or site. 2. Specifically, the average parasite load of an entire host population (including uninfected individuals).
Abyssal Referring to the deepest part of the ocean.
Abyssal plain A large, relatively flat area of the ocean bottom, typically 2000 to 6000 m in depth.
Acceptance A behavior pattern in which hosts treat brood parasitic eggs as if they were their own eggs.
Accidental epiphyte A plant that normally grows terrestrially but that occasionally grows to maturity on or in a tree.
Acclimation 1. Another term for ACCLIMATIZATION (see next). 2. Specifically, a process of acclimatization that occurs in a controlled, experimental setting, such as a laboratory.
Acclimatization Reversible physiological or morphological changes that an organism experiences in response to changing environmental conditions. Such physiological changes enable the organism to tolerate (acclimatize to) the new environmental conditions.
Accounting price See SHADOW PRICE.
Accretionary Accumulating; describing a gradual increase or growth, as of sand on a beach.
Acetylcholinesterase (AChE) The enzyme responsible for breaking down the neurotransmitter acetylcholine (ACh) at nerve synapses, thereby preventing hyperexcitation of cholinergic pathways in the nervous system. The target of organophosphate and carbamate insecticides.
Acid deposition Anthropogenic acidification of terrestrial and freshwater ecosystems by (primarily) sulfuric acid, derived from sulfur dioxide produced by burning oil and coal and deposited in rain and snow (**acid rain**), directly as particles (**dry deposition**) and as cloud droplets.
Acid neutralizing capacity (ANC) The amount of strong acid that is required to decrease the pH of water to a defined chemical end point. Acid neutralizing capacity is measured in units of $\mu eq\ l^{-1}$. It is a measure of the ability of water to neutralize inputs of strong acids.
Acidification The process of soil or water becoming more acidic, with a loss of base cations (calcium, magnesium, potassium) and an increase in hydrogen and aluminum ion concentrations, resulting in losses of plant biodiversity and dominance by acid-tolerant species.
Acidophilic Acid-loving; describing organisms that prefer or require a low pH environment. Such an organism is an **acidophile**.
Acidophytic, Acidophyte Alternate form of ACIDOPHILIC, ACIDOPHILE (see previous).
Acid-sensitive Describing an area with low supply rates of acid-neutralizing basic cations. These areas generally occur in high-elevation forest regions and are characterized by shallow soil.
Acquisition costs The costs of acquiring property rights to a parcel of land. This can be total (if the land and title are sold to a conservation agent) or partial. Partial transfers of property rights include short-term rental, conservation easements, and contracts between conservation agents and land owners who exchange money for land management that enhances conservation value.
Active restoration A process of actively assisting a system in recovery beyond simply removing the disturbance.
Acute Describing an exposure to an environmental stress that is brief in relation to the temporal scale of the biological system exposed.
Acute toxicity A damaging effect caused by a single short period of exposure to high concentrations of a pollutant.
Adaptation 1. In general, characteristics or behavior patterns of an organism that suit it to its conditions of existence. 2. Specifically (under the theory of descent with modification), a derived feature of an organism that increases the survival and reproductive success of the organism by virtue of the possession of that feature.
Adaptationism The doctrine that all important evolutionary processes are dominated by natural selection, and that all significant biological characters increase an organism's fitness.
Adaptive radiation The evolution of ecological and phenotypic diversity within a rapidly multiplying lineage.
Adaptive shift A change in the nature of a trait (morphology, ecology, or behavior) that enhances survival and/or reproduction in an ecological environment different from that originally occupied by the organism.
Adaptive syndrome A coordinated set of adaptations.
Additionality The achievement of environmental gains beyond what would have occurred under usual conditions.
Adipocytes 1. **Brown adipocytes**. Specialized thermogenic cells unique to mammals and probably derived from skeletal muscle, containing numerous mitochondria and small droplets of triacylglycerols. Under neural and endocrine control, brown adipocytes can switch rapidly from inactivity to the highest known metabolic rate, generating heat from oxidation of fatty acids and/or glucose in mitochondria uncoupled from ATP synthesis by uncoupling proteins. 2. **White adipocytes**. Large cells unique to vertebrates that store triacylglycerols, take up and release fatty acids, and produce various signal molecules and receptors that enable them to respond to circulating and locally acting agonists.
Adipose fin A small, fleshy fin without supporting spines or rays, set far back on the dorsal surface of many catfish, salmon, characins, and other groups.
Adipose tissue Storage tissue unique to vertebrates and best developed in tetrapods, consisting almost entirely of expandable adipocytes (see above) that contain a large droplet of triacylglycerols, along with vascular and neural tissue, and often contiguous or interchelated lymphoid tissues.

Advective precipitation A process in which moist air passes over cool ground by advection (wind) and is cooled.
Aeolian Wind-blown; relating to or caused by the action of the wind.
Aeolianites Wind-deposited sediments.
Aerenchyma Porous root tissue, especially well developed in wetland plants, that allows diffusive flux of oxygen from above-ground tissues to root tips. This tissue supports both the respiratory demand of the root tissues and allows oxygen to leak into the surrounding soil.
Aerial root In mangrove species such as Rhizophora, a root branching out from the stem some distance above the soil surface. Lenticels (pores) in the aerial portion of these roots enable gas exchange to take place, through aerenchyma tissue (see previous), with the respiring underground portions of the root.
Aerobe An organism that utilizes or requires the presence of oxygen for growth.
Aerobic 1. Occurring in the presence of oxygen. 2. Utilizing or requiring oxygen for growth.
Aerosols Microscopic airborne particles.
Affiliative behavior Behavior that is supportive and brings individuals together.
Afforestation The process of planting trees in areas currently devoid of them; e.g., in desert regions or a previously wooded area that had been converted to cropland or pasture.
Afrotropical One of the major zoogeographical regions of the world. See ZOOGEOGRAPHICAL REGION.
Agonistic behavior Behavior that is associated with fighting and competition in some way, as by individuals competing for the same resource; it may be aggressive, threatening, or submissive.
Agricultural intensification See INTENSIFICATION.
Agricultural land See PRIME AGRICULTURAL LAND; DEGRADED AGRICULTURAL LAND.
Agrobiodiversity 1. The variety and variability of living organisms that contribute to food and agriculture in the broadest sense, and that are associated with cultivating crops and rearing animals within ecological complexes. 2. More generally, all the organisms present in an agricultural landscape.
Agroecosystem Any ecosystem under agricultural management practices, as for purposes of food, fiber or biofuel production.
Agroenergy The production of biofuels as plant crops in agriculture, as distinct from biofuels produced synthetically or from algal culture.
Agroforestry A collective name for land-use systems and practices in which woody perennials are deliberately integrated with crops and animals on the same land management unit. This integration can be either in a spatial mixture or in a temporal sequence.
Agroscape A collective term for the agricultural, ranching, and plantation countryside, with its roads, irrigation ditches, buildings, and so on; contrasted with the wildland countryside that is not directly managed by humanity (though strongly impacted by it). The agroscape intergrades with wildlands in the form of woodlots, abandoned fields, poor soil sites, hedgerows, and edges of wildlands.
Air pollution Lowering of air quality due to the release of toxic materials by factories, automobiles, fires, and other human activities.
Airshed By analogy with a watershed, a definable area of the atmosphere that has commonality with respect to the dispersion of emissions; all parts of an airshed (e.g. the area around a power plant) are exposed to similar conditions of air pollution.
Alate An imago (adult insect) still possessing its wings.
Albedo The fraction of light hitting a surface that is then reflected from the surface.
Alevin A life cycle stage in salmon in which they are newly hatched with an unabsorbed yolk sac from which they obtain nourishment.
Algae (singular **alga**) Primitive plant-like organisms that generally obtain energy through photosynthesis. These organisms can be unicellular, filamentous, or colonial microscopic forms (**microalgae**), or they can be macroscopic (**macroalgae**) consisting of a primitive plant body (thallus) that lacks vascular tissue in most species.
Algal Having to do with or belonging to the algae (see previous).
Algal bloom A rapid increase in algae population in an aquatic system, freshwater or marine; so called in analogy with the blooming of flowers. Can result from higher concentrations of nutrients (particularly phosphorus and nitrogen) in waters, leading to increased growth of algae and green plants. A **harmful algal bloom (HAB)** is such an event involving toxic or otherwise harmful phytoplankton, which presents an environmental or public health threat.
Alien 1. A species or organism in a given area in which it does not naturally occur, present there because it has been intentionally or accidentally introduced from another region or ecosystem as a result of human activities. May also be described as *exotic*, *non-indigenous*, or *non-native*. 2. Having to do with or being such a species or organism.
Allee effect A positive association between average individual fitness and population size over some finite interval. For example, the growth rate of a population may be reduced at low densities, as from the increased difficulty of finding a mate. [Described by U.S. ecologist Warder Clyde Allee, 1885–1955.]
Allele One of two or more different forms of a gene.
Allelochemical A bioactive secondary metabolite with no known major function in primary metabolism but with the capacity to affect the growth, survival, or behavior of target organisms. Many allelochemicals act as chemical defense agents, although they may also mediate beneficial interactions with the targets.
Alley cropping See CONTOUR HEDGEROW INTERCROPPING.
Allochthonous Originating in a place other than that where it is now sited; e.g., outside the ecosystem where it is found.
Allometric Having to do with or exhibiting allometry (see next).
Allometry The relationship between a given biological feature and body mass. For example, basal metabolic rate varies with body mass raised to the power three-quarters, rather than in direct proportion with body mass, so that an animal twice as large does not need twice the amount of food to supply its metabolic needs.

Allopatric Describing populations, species, or taxa occupying separate, non-overlapping geographical areas.
Allopatric speciation The process of genetic divergence between geographically separated populations, leading to distinct species.
Allopatry The fact of populations, species, or taxa occupying different geographical areas.
Allopolyploid 1. Having two or more dissimilar chromosome sets derived from interspecific hybridization and chromosome doubling. 2. An organism of this type.
Alluvial fan An aggregation of fine sediments forming a conical fan when deposited by streams or rivers.
Alpha (α) diversity The diversity of species, often estimated as species richness, within a local community or site. Compare BETA DIVERSITY; GAMMA DIVERSITY.
Alpine Referring to the life zone above the climatic high-elevation tree line, irrespective of latitude. Though originally describing the Alps mountain range of Europe (from a pre-Roman word for high mountains), the term is now applied globally.
Altruism Behavior that reduces the agent's lifetime reproductive fitness while enhancing that of another or others in the same population. Such behavior is **altruistic**.
AMO Atlantic Multidecadal Oscillation.
Ammonites An extinct group of shelled invertebrates related to modern octopus, squid, and nautilus; their fossils are often referenced to identify geologic time periods.
Amniota The taxon of vertebrates that includes mammals, birds, and reptiles (including extinct relatives). So called because they possess a set of protective membranes for the embryo: the *amnion*, chorion, and allantois.
Amniote One of the Amniota (see previous).
Amniotic Relating to the amnion, or an organism possessing this (see AMNIOTA above).
Amphibian A member of a class of vertebrates (the **Amphibia**), comprising frogs and toads (order Anura), newts and salamanders (order Caudata), and caecilians (order Gymnophiona). Amphibians typically return to water to breed and pass through an aquatic larval stage with gills. They have a moist skin without scales, which is permeable to water and gases.
Amphibite A species requiring both surface waters and subterranean waters to complete its life cycle.
Amplification host A species that increases the rate of transmission of pathogens.
AMS date Accelerator Mass Spectrometry date; a radiocarbon date obtained by directly measuring the amount of carbon 14 in a sample with an accelerator mass spectrometer.
Anadromous Describing aquatic organisms that spawn and undergo early development in fresh water, migrate to sea to grow and mature, and then return to freshwater to reproduce; e.g., salmon, lampreys, sturgeons. Contrasted with CATADROMOUS.
Anadromy The fact of being anadromous (see previous).
Anaerobe An organism able to grow in the absence of oxygen.
Anaerobic 1. Occurring without the presence of oxygen. 2. Not requiring oxygen for growth.
Anagenesis Evolutionary changes occurring within an ancestor–descendant lineage. Contrasted with CLADOGENESIS.
Anamniotic Describing organisms (e.g., frogs) whose eggs are not surrounded by the complex protective membranes that distinguish the amniotic eggs of reptiles, birds, and mammals (the Amniota).
ANC Acid neutralizing capacity.
Ancestral 1. Describing a trait or condition that appears in an ancestor and also in a descendant species. 2. Describing taxa with such traits or conditions.
Anchialine Describing haline (salty) water, usually with restricted exposure to open air, and always with subterranean connections to the sea. Also, **anchihaline**.
Ancient lake Classification for a lake with a persistence of more than 100,000 years.
Andepts Soils derived from andesitic (high mountain) volcanic ash; so called because associated with the Andes mountains.
Angiosperms Flowering vascular plants in which the seeds, which are produced from the ovules of the flowers, are enclosed in fruits developed from the matured ovaries; the largest class of vascular plants, as opposed to cryptogams (mosses, etc., which do not produce seeds) and conifers (in which the seeds are not enclosed in fruits).
Anhydrobiosis An ability of certain organisms to lose virtually all water from their bodies under certain adverse conditions, yet remain viable when subsequently rehydrated.
Animal unit month (AUM) A measurement expressed as the quantity of forage needed to sustain one 1000-lb cow or five sheep for one month; used to manage grazing livestock.
Anion A negatively charged atom or molecule.
Annelid One of the Annelida, a large, relatively species-poor phylum of segmented worms.
Annual A plant that survives year to year as a seed rather than as a mature plant.
Anoxia A condition in which little or no oxygen is present.
Anoxic 1. Lacking oxygen. 2. Specifically, describing ocean or fresh waters that are depleted of dissolved oxygen.
Antennae (singular **antenna**) Paired sensory appendages on the head of arthropods. In crustaceans the first pair are also known as **antennules**.
Anthropocene The current era beginning with the Industrial Revolution, characterized by the increasingly significant impact of human activities on the Earth's biodiversity, land cover, biogeochemical cycling, water quality and availability, and other major features.
Anthropocentric Human-centered in perspective, especially with regard to the inherent value of the natural world.
Anthropocentrism The position that only human beings have moral worth or intrinsic value.
Anthropochoric Geographic distribution due to human agency.
Anthropogenic 1. Caused by humans; resulting from human activities. 2. Specifically, referring to environmental effects or changes caused or influenced by human activity; e.g., global warming.
Apex predator A predators that has no predator of its own and thus occupies a food web's highest trophic level.
Aphyllous Having no leaves; leafless; e.g., most cactus plants.
Apomictic Having to do with or involving apomixis (see next).

Apomixis (plural **apomixes**) A mode of clonal propagation by seeds, the embryos of which are totally genetic copies of the source plant. Seeds are produced without fertilization, but often pollination is required to induce apomictic seed production. Apomictic plants can also reproduce sexually, but this is very rare.
Apomorphic Describing derived characteristics, relative to a sister group.
Apomorphy A derived character or character state.
Aposematic Describing an organism that is rendered less susceptible to predation by somehow making known its obvious unpalatability, as by conspicuous odors, sounds, or coloration. The fact of doing this is **aposematism**.
Apparent competition An indirect interaction between two prey species in which one experiences more intense predation, because the presence of the other brings about a change in predator abundance or behavior.
Aquaculture The commercial farming of aquatic organisms, including fish, mollusks, crustaceans, and aquatic plants.
Aquifer A geological formation that contains groundwater and allows its movement.
Arboreal 1. Having to do with or involving trees. 2. Living in or on trees.
Arboricolous Growing on or living in trees, or off the ground in large woody shrubs or on fallen tree trunks.
Archaea Microorganisms that are similar to bacteria in size and simplicity of structure but very different in molecular organization, often living in extreme environments. They comprise (in addition to eukaryotes and bacteria) one of the three domains of life.
Archaic ungulate One of an extinct group or grade of mammals that possibly gave rise to hoofed mammals. Also known as a CONDYLARTH.
Area cladogram A branching diagram that uses phylogenetic relationships to trace geographical changes (either dispersal events or barriers to dispersal).
Area of endemism An area characterized by the congruent distributions of two or more groups of organisms.
Arid Describing a climate lacking in moisture, especially one having insufficient rainfall to support many trees or woody plants. Such a condition is **aridity**.
Arrhenotokous Describing a reproductive mode in which unfertilized eggs develop into haploid males and fertilized eggs develop into diploid females. This mode is **Arrhenotoky**.
Arthropod One of the Arthropoda, the phylum of joint-legged animals including insects, spiders, crustaceans, and others; the most species-rich phylum existing today.
Artificial ecosystem An ecosystem dominated by human artifacts and human-induced materials and energy flows.
Assemblage The collection of animals and plants found together in a patch of habitat.
Assisted colonization The translocation of species outside of their native range to allow them to track changes in climate.
Associational refuge A situation in which a potential prey escapes or deters a consumer by associating with another organism, thus interfering with the ability of the consumer to locate or attack the prey.
Assortative mating The tendency of like to mate with like, whether it is based on similarities in genotypes or similarities in phenotypes.
ATBI All taxa biodiversity inventory; the thesis, first suggested by D. H. Janzen, that it might be feasible to produce a complete species list for all the organisms living in one place; e.g., a hectare of tropical forest. This goal has thus far proved elusive.
Atlantic Multidecadal Oscillation (AMO) A mode of variability occurring in the North Atlantic Ocean, principal expressed in the sea surface temperature (SST).
Atmospheric deposition The process by which materials are deposited from the atmosphere to the Earth's surface.
Atmospheric lifetime A time scale describing the rate of removal of a gas from the atmosphere, generally defined as the time for a 63.2% decrease (the e-folding time) in the global atmospheric burden of the gas; a period of many years for major greenhouse gases.
ATP synthetase A membrane-associated protein complex that couples exergonic fluxes of $H+$ across the membrane to ADP phosphorylation, or vice versa.
AUM Animal unit month.
Australasian One of the major zoogeographical regions of the world. See ZOOGEOGRAPHICAL REGION.
Autapomorphy An advanced or derived character state unique to an individual taxon (of any rank).
Autocatalysis The self-acceleration of certain chemical reactions that yield catalytically active products. The reaction rate of autocatalytic processes increases exponentially.
Autochthonous Referring to the production of organic matter within an ecosystem, for example, primary production by aquatic plants.
Autogenic Describing a species that creates habitat for other organisms, in a habitat that would not exist for them if the autogenic species were not present.
Autotroph Literally, a self-feeder; an organism that is able to utilize inorganic carbon (carbon dioxide) as the sole carbon source for growth; for example, green plants and certain bacteria. Such an organism is **autotrophic**.
Autotrophy The ability of organisms to grow and reproduce independent of external sources of organic carbon compounds. Compare HETEROTROPHY.
Avirulent Not virulent; describing a parasite that has little impact on its host's fitness.
AZA Association of Zoos and Aquariums, a North American professional organization.
Background extinction (rate) The natural rate of extinction over geological time, measured from the fossil record and independent of anthropogenic influence; characteristic of the major part of the evolution of life.
Background selection Selection that takes place at loci other than that of interest. Such events can strongly increase the intensity of genetic drift as well as hinder the action of selection at a locus of interest. These effects are normally modeled by reducing the effective population size applicable to the locus of interest.
Bacteria (singular **bacterium**) An entirely microbial domain of single-celled organisms, existing in various shapes and generally found throughout the Earth as well as in organic matter and the living bodies of humans and other organisms. They are evolutionarily distinct from Archaea, and one of the three domains of life along with Archaea and Eukaryota.
Bacteriophage A virus that infects bacteria.

Baiji A freshwater marine mammal, *Lipotes vexillifer*, living in China's Yangtze River; last verifiably observed in 2002 and now regarded as extinct after an extensive 2007 search failed to find any specimens. This would be the first known extinction of a cetacean species in recorded human history. Also known as a **Yangtze (River) dolphin** or **Chinese river dolphin**.

Baleen Modified, hardened epithelial structures suspended from the upper jaws of mysticete whales, having the form of multiple elongate plates with a fibrous fringe on the inside edge. They allow whales to filter zooplanktonic or fish prey from sea water.

Band The basic economic, social, and political unit of a hunter-gatherer society.

Barophile An organism able to survive in conditions of extreme atmospheric pressures, at great depths of the ocean or solid earth. **Barotolerant** organisms can survive at up to 400 atm below the water or earth, but grow best at 1 atm. **Barophilic** organisms grow best at higher pressures, up to 500–600 atm. **Extreme barophiles** grow best at depths of 700 atm or more. (Each gradient of one atmosphere in the ocean is equal to 10 feet below the surface.)

Barophilic Literally, pressure-loving; describing an organism able to endure high atmospheric pressures; e.g., certain microorganisms living at great ocean depths. See BAROPHILE (previous).

Barotolerant See BAROPHILE.

Basal 1. Designating a species that eats no other species and thus represents the first part of a food web. 2. Having to do with or describing such a species: *basal* plants.

Basal metabolism The minimum amount of energy expended by an adult animal that has not eaten recently, at normal body temperature during rest (usually sleep).

Basement complex The layer of highly metamorphosed sedimentary rocks, mainly of late Pre-Cambrian age, that underlies much of tropical Africa.

Batesian mimicry A form of mimicry in which the target organism is rendered less susceptible to predation by its resemblance in morphology or coloration to a different species that is dangerous or unpalatable to the predator. [Described by English naturalist Henry Walter Bates, 1825–1892.]

Batha A traditional term for semishrub communities, mainly of seral vegetation of old field succession, in the Mediterranean area of the Near East.

Beneficial management practice (BMP) Any of various methods to prevent or reduce the movement of sediment, nutrients, pesticides, and other chemical contaminants from the land to surface or groundwater, or otherwise to protect water quality from the adverse effects of agricultural activities.

Bennettitales (Cycadeoidales) An order of extinct gymnosperms composed of two families having both unisexual and bisexual reproductive structures.

Benthic 1. Relating to or located on the bottom of the sea or another aquatic environment such as a freshwater lake, river, or stream. 2. Living at the bottom of a body of water: a *benthic* organism.

Benthos 1. Those organisms living on, in, or near the seabed or at the bottom of some other aquatic environment, including those that reside on hard and soft bottom surfaces and others that reside between sediment grains. 2. The area at the bottom of the sea or another body of water.

Beringia The so-called Bering Land Bridge, a region at the northwestern corner of North America separated from Asia only by the shallow waters of the Bering Strait. When ocean levels declined during glaciation, Asia and North America were connected by land in this region; thus it is theorized to be the means by which humans migrated from Asia to the Americas.

Beta (β) diversity The degree of turnover in species (and changes in their abundances) among communities or sites along a gradient or within a larger area. Compare ALPHA DIVERSITY; GAMMA DIVERSITY.

Bet-hedging A strategy of an organism, living in a variable environment, that leads to low variation in fitness. In general, such a trait provides the organism greater net fitness over a range of environmental conditions than would a trait specialized for a single environment. A **bet-hedging trait** is expected to evolve when the environment in which a species lives fluctuates over a fixed range of conditions that is sufficiently broad for fitness to vary significantly, and when it is unpredictable which state the environment will take in the immediate future.

Between-habitat diversity The degree of dissimilarity in species composition between two habitats; the greater the number of species shared by two habitats, the lower the between-habitat diversity.

Big bang reproduction See SEMELPARITY.

Binomen A two-part name of a species, consisting of the name of the genus in which it is placed, followed by a word peculiar to that species.

Binomial nomenclature The scientific practice of naming species by a two-part combination of a specific epithet preceded by the genus to which the species belongs; e.g., *Ectopistes migratorius*, the passenger pigeon.

Bioaccumulation The accumulation of toxicants or contaminants, such as mercury, by successive organisms in a food chain.

Bioassay The use of living cells or organisms to make measurements of the amounts or activity of toxins or other substances.

Biocentric Valuing the existence and diversity of all biological species.

Biocentrism The belief that all living beings have moral worth or intrinsic value.

Biochemical oxygen demand (BOD) A measure of the amount of dissolved oxygen required by the microbial community to decompose organic matter by aerobic metabolism.

Biocontrol See BIOLOGICAL CONTROL.

Biocultural axiom The concept that biological and cultural diversity are mutually dependent and geographically coterminous.

Biocultural diversity The diversity of life in all its manifestations, in both the biological and cultural realms, which are interrelated (and likely have coevolved) within a complex social–ecological adaptive system.

Biodiesel A liquid biofuel used as a substitute for, or an additive to, standard diesel fuel.

Biodiversity (abridged from **biological diversity**) The full diversity of life on Earth, encompassing all levels of biological

organization, from molecules to genes, to populations, to species, to ecosystems and the entire biosphere. It is a multidimensional concept difficult to measure, and in practice most focus is on diversity at the species level.

Biodiversity assessment The identification and classification of species, habitats, and communities within a given area or region; can be done to evaluate whether management is necessary to conserve biological diversity.

Biodiversity hotspot See HOTSPOT.

Biodiversity offset A measures intended to compensate for adverse biodiversity impacts, with the goal of no net loss and preferably a net gain of biodiversity of species composition, habitat structure, and ecosystem function.

Biodiversity restoration See RESTORATION.

Bioelectricity 1. An electric current generated by living tissue. 2. Electricity produced by burning biomass.

Bioenergetics The flow and transformation of energy within organisms, or between organisms and their environment.

Bioenergy A form of energy that can be extracted from biomass, including biodiesel from fats and oils, bioethanol from sugars, starches, and lignocellulosic material, and bioelectricity and bioheat from the combustion of lignocellulosic material.

Bioethanol Alcohol made from sugar (e.g., sugarcane), starch (e.g., corn grain), or cellulosic materials (e.g., cornstalks, wheat straw, prairie grasses, and trees) for use as a biofuel; sugar and starches are converted to ethanol through fermentation, while cellulosic material is converted via enzymatic hydrolysis or synthesis gas fermentation.

Biofuel Any of a variety of fuels in some way derived from biomass, including firewood, methane, or liquid transportation fuels obtained from plants or other biological materials.

Biofuel land-use change The conversion of forest land and pasture to cropland for the purpose of growing plants for biofuel. The anticipated reduction in GHG emissions resulting from the substitution of biofuel for traditional fossil fuels is thus offset by release of carbon from biomass and soils, and there are a variety of other impacts such as loss of biodiversity and overexploitation of water resources, as well as market effects such as higher food prices (and possible food scarcity) due to reduction in the amount of land devoted to food crops.

Biogeochemical processes The various chemical, physical, geological, and biological processes that collectively govern the composition of the biosphere.

Biogeochemistry The scientific study of biotic controls on the chemistry of the environment and geochemical controls on the structure and function of ecosystems.

Biogeographic realm One of the largest divisions of the historic and evolutionary patterns of terrestrial plants and animals. In such an area, plants and animals evolved in the isolation created by barriers such as oceans, mountain ranges, or deserts. It can be a single continent, or it can span continents.

Biogeographic region 1. A large region with characteristic assemblages of natural communities and species, distinct from other regions. 2. See BIOGEOGRAPHIC REALM.

Biogeography The study of the geographic variation of nature, including variation in any biological characteristics (e.g., body size, population density, or species richness) on a global scale. **Historical biogeography** studies this variation over time.

Bioheat 1. A fuel or heating system based on or employing a biological source. 2. Specifically, a fuel composed of conventional heating oil blended with a percentage of biodiesel (typically 2–20%).

Biological assay See BIOASSAY.

Biological carbon pump See CARBON PUMP.

Biological control The use of naturally occurring or introduced natural enemies (e.g., predators and parasitoids) to control agricultural pests, as opposed to non-natural controls such as insecticide sprays.

Biological diversity See BIODIVERSITY.

Biological energetics See BIOENERGETICS.

Biological integration The fact of life functions being organized in distinct, self-regulating units (cells, tissues, organs, organisms, populations, communities, and ecosystems).

Biological soil crust The combination of non-vascular and non-seed-forming plants that commonly occur on the soil surface of many arid and semiarid ecosystems. May consist of mosses, lichens, liverworts, green algae, and cyanobacteria.

Bioluminescence The production of light by living organisms; e.g., fireflies, anglerfish.

Biomass 1. The combined mass or weight of all the members of a given population or stock at a given time, or, on the average, over a certain time period. 2. The mass of biological material remaining after the removal of water from it by oven-drying at 70–100 °C; often expressed as mass per area of ground surface. **3**. A collective term for all organic substances that can be used as energy sources, including wood, straw, agricultural and industrial plant residues, municipal organic wastes, and crops grown specifically for fuel. Applies to relatively recent (non-geologic) fuel sources, excluding fossil fuels.

Biomass pyramid A graphic representation of the biomass relationships of a community, in which the total amount of biomass at each successive trophic level is proportional to the width of the pyramid at the appropriate height.

Biome A major terrestrial ecological community and landscape type, characterized by more or less uniform physiognomy of its potential natural vegetation and with characteristic fauna and flora, such as the tropical rainforest, the warm deserts, or the temperate grasslands.

Biomimetic 1. An artificial compound, device, or structure that mimics or was inspired by nature. 2. Imitating or modeled after nature or a natural process. **3**. Having to do with or employing biomimetics (see next).

Biomimetics The study of natural structures, processes, and systems as a model for human technology. Also known as **biomimicry**.

Bionomic equilibrium In a biological common property resource, an equilibrium between resource production rate and exploitation rate, characterized by the dissipation of economic rents.

Bionomics The mode of life of a species.

Biophilia The innate tendency of humanity to focus on life and lifelike processes and to have an affinity for the natural world, said to have evolved over millennia and to be part of human inheritance.

Bioquads An occurrence record of organisms used in biodiversity research, consisting of four elements: species names, location, time, and source.
Bioregion Another term for a BIOGEOGRAPHIC REALM or REGION.
Biosafety Efforts to reduce and eliminate the potential risks of biotechnology and its products.
Biosphere 1. All the plants and animals on Earth, together with the habitat they require for long-term survival. 2. The portions of the Earth inhabited by living beings.
Biosphere reserve A specific area of land or water identified as part of an international conservation program to protect representative ecosystems throughout the world in ways compatible with sustainable development. The program is administered by the United Nations World Network of Biosphere Reserves.
Biosynthesis The biochemical process by which a plant produces molecules of utility or adaptation.
Biota Fauna and flora; the totality of organisms in a given place.
Biotic 1. Having to do with the living components of an ecological community (organisms, species). 2. Having to do with life; living.
Biotic homogenization the process by which the genetic, taxonomic, or functional similarities of regional biotas increase over time.
Biotic impoverishment The decline of a species to the point of having little or no ecological significance.
Biotic interaction A situation in which the growth or behavior of one species affects another species; such interactions can be antagonistic (e.g., competition for limiting resources, predation, herbivory, or parasitism) or facilitory (e.g., pollination or other forms of mutualism).
Biotic similarity A measure of the degree to which two or more samples or assemblages are similar in species composition. This can be expressed by any of various **biotic similarity indices**.
Biotope A region that is distinguished by particular environmental conditions (climate, soil, altitude, etc.) and thus contains a characteristic assemblage of organisms.
Biotopic Having to do with or constituting a biotope (see previous).
Biramous Relating to or having an extension of the body (usually an appendage) with two branches.
Bivoltine 1. A species with two generations per year. 2. describing such a species.
Black box An informal term for an entity that can be examined at the system level without specifying its internal contents.
Black-water A term for Amazonian rivers that are dark because of dissolved tannic matter and are acidic (pH about 4).
Bleaching The loss of symbiotic zooxanthellae (photosynthetic algae) from corals. Bleaching is usually caused by elevated sea surface temperatures, but it can also be caused by low temperature, sedimentation, extreme salinities or light levels, and bacterial infection.
Bloom See ALGAL BLOOM.
Blubber Specialized superficial adipose tissue found only in pinnipeds (seals), cetaceans (whales and dolphins), and sirenians (sea-cows), serving as thermal insulation as well as for energy storage.
blue–green algae Former name for the CYANOBACTERIA.
BMP Beneficial management practice.
BOD Biochemical oxygen demand.
Bog An acidic peat land that receives all water inputs from the atmosphere and hence has low pH (usually 3.4–4.6), low alkalinity, and negligible concentrations of base cations in surface waters; typically dominated by mosses of the genus Sphagnum and other plants that are able to tolerate low pH and low nutrient availability; i.e., the heath family (Ericaceae).
Booklungs In arachnids, one to four pairs of abdominal respiratory organs consisting of a thin, multi-folded membrane (the book's "pages") over which blood circulates and that is open to an air-filled cavity on the outside, itself open to the exterior via a spiracle. Gases passively diffuse back and forth across the membrane.
Boreal Relating to the northern high latitudes (but not polar), regions that contain large continental landmasses and thus continental climates with moderate summers and long, severely cold winters. [From Greek *boreas*, the north wind.]
Boreal forest A forest zone dominated by coniferous species, covering the northern latitudes of North America, the Nordic countries, and Russia.
Bottom-up 1. Describing a process in which physical parameters (such as nutrients) allow increased primary productivity and the effects of this cascade up through higher trophic levels; e.g., nutrient additions to a lake resulting in increased phytoplankton growth, this increasing resource of food allowing increased number of herbivorous zooplankton, and the abundance of zooplankton leading to increased densities of zooplankton-eating fishes. 2. Describing impacts or controls on urban biodiversity that originate from human actions at smaller scales, such as household or neighborhood scales. Thus, **bottom-up effect** or **force**. Compare TOP-DOWN.
Brachyodont A low-crowned cheek tooth commonly found in omnivorous or burrowing animals.
Brachypterous Having rudimentary or unusually short wings.
Brackish Describing water that is saline but less salty than seawater, as when fresh and salt water mix in an estuary.
Breed 1. A subgroup within a species distinguished from similar subgroups by identifiable external characteristics, typically developed by managed reproduction; e.g., the Brahman or Angus cattle breeds. 2. To cause an animal or plant to produce offspring in a controlled manner.
Brood parasite An organism (e.g., certain birds) that makes use of individuals of the same or another species for the rearing of its young; a strategy known as **brood parasitism**.
Broodstock Fish or shellfish from which a first or subsequent generation may be produced in captivity, whether for growing as aquaculture or for release to the wild for stock enhancement.
Brown adipocytes See ADIPOCYTES.
Browse 1. Leaves, twigs, or reproductive parts of shrubs, woody vines, and trees available for animal consumption. 2. The act of consuming such plant parts. 3. To consume plants in this manner.
Bryophyte A nonvascular plant of the division Bryophyta (a moss, liverwort, or hornwort).

BS Bundle sheath.
Bulk density The mass of undisturbed dry soil per unit volume; a measure of soil compaction.
Bundle sheath (BS) tissue A cell layer at the periphery of the vascular bundles in leaves. In C4 plants, the reactions of the photosynthetic carbon reduction cycle are localized in this layer, in contrast with C3 plants where they occur in the mesophyll tissue. In comparison to C4 species, the BS cells of C3 species are small, with few chloroplasts.
Bush-fallow cropping An agronomic system in which soil fertility is maintained by allowing native vegetation to regenerate following several years of cropping.
Bushmeat Primates or other wild animals hunted illegally for food or income.
Bycatch Unwanted fish or other living creatures caught unintentionally in fishing gear during an effort to catch something else, and then discarded; also called **bykill** if discarded dead.
C3 plant A plant in which carbon dioxide is first fixed into a compound containing three carbon atoms before entering the Calvin cycle of photosynthesis. Most trees and temperate plants are C3 plants.
C4 plant A plant in which carbon dioxide is first fixed into a compound containing four carbon atoms before entering the Calvin cycle of photosynthesis. Most tropical grasses are C4 plants.
Caatinga A native South American word for an open place; applied to semi-arid ecosystems of eastern South America.
CAFO Concentrated animal feeding operations; a feeding facility that confines animals for more than 45 days in an area that does not produce vegetation during the growing season.
Calanoid copepods Zooplankton belonging to the Crustacea, very abundant in ocean waters. They play a major ecological role in the food web of the pelagic ecosystem as grazers of phytoplankton and as a food source (e.g., for larval and adult fish).
Calcareous 1. Mostly composed of calcium carbonate ($CaCO_3$). 2. Specifically, describing soils with high calcium carbonate content, which buffers them against changes in pH.
Calcareous fen 1. A peat-accumulating wetland with surface deposits of calcium carbonate and a distinctive flora of calciphilic species. Such wetlands typically develop where substantial amounts of cold, calcium-carbonate rich groundwater discharge to the surface. 2. More generally, any wetland with a high calcium carbonate content in its water and soils.
Calciphilic Describing a plant or other organism that thrives in a calcium-rich environment. Such an organism is a **calciphile**.
Cambrian explosion A term for the period of time from about 570 million to 530 million years ago during the Cambrian geological period, when the diversity of multicellular life greatly increased in a relatively short time (by the standards of geologic time). Also known as the **Cambrian radiation**.
CAM metabolism Crassulacean acid metabolism; a carbon uptake system utilized by many succulent plants. These plants fix carbon dioxide during the night when evapotranspiration is relatively low, storing it as organic acids. The stored CO_2 is then released during the day and refixed in the typical light reactions of photosynthesis, thereby increasing water use efficiency.
Canopy The highest tree layer in the vertical stratification of forests. The herbaceous foods for canopy-dwelling animals are found among the branches and leaves of the canopy.
Cap and trade A market-based incentive for businesses or other entities, setting an environmental target such as a maximum amount of pollution or minimum quantity of habitat preservation (the "cap"), and allowing this compliance obligation to be exchanged across firms to meet the objective at lowest cost (the "trade").
Capoeira A Brazilian term for secondary forest on cleared ground.
Captive breeding Human-mediated breeding and rearing of wildlife under controlled conditions, as in a zoo.
Carbon capture See CARBON SEQUESTRATION.
Carbon cycle The process by which carbon moves among its major reservoirs (atmosphere, terrestrial biosphere including freshwater systems, soil, oceans, sediments, and so on) by various chemical, physical, biological, and geological processes. These movements may be natural flows (e.g., plant respiration) or the result of human activity (e.g., burning of fossil fuels). The carbon cycle plays a key role in global climate because carbon dioxide is a major contributor to the greenhouse effect (see).
Carbon footprint 1. The total amount of carbon dioxide and other greenhouse gases produced to directly and indirectly support human activities. 2. The amount of this associated with one specific entity, such as a nation, city, building, or residence, or an individual person. See also ECOLOGICAL FOOTPRINT.
Carbon pump The biologically mediated transfer of carbon in the Earth's oceans from the euphotic (uppermost) zone to the ocean's interior, maintaining a vertical gradient in inorganic carbon concentrations. Major processes involved in the pump include photosynthetic consumption of inorganic carbon and production of organic matter in the euphotic zone, gravitational settling of particulate organic matter, and subsequent remineralization of organic matter back to inorganic carbon at greater depths.
Carbon sequestration The process of removing carbon dioxide from the atmosphere and rendering it inaccessible to carbon-cycling processes (and thus mitigating climate change), as by reforestation.
Carbon sink See SINK.
Carboxylase An enzyme that catalyzes the formation of a C–C bond between inorganic C (CO_2 or HCO_3^-) and an organic molecule.
Carnivorous Describing an organism that obtains its food by consuming other animals, especially one that does so exclusively or mainly in this manner. Such an organism is a **carnivore**.
Carnivory The fact or process of feeding exclusively or mainly on the flesh of other animals.
Carrying capacity The maximum population that can be sustained indefinitely in a given area without changing the ecosystem in ways that will eventually reduce the sustainable population. This balance between population and resources is a dynamic one that involves changes in technology and other factors.

Caste A group of individuals in a colony that are both morphologically distinct and specialized in behavior.
Catadromous Describing aquatic organisms that spawn and undergo early development in the ocean, migrate to fresh water to grow and mature, and then return to the ocean to reproduce; e.g., freshwater eels, some mullets. Contrasted with ANADROMOUS.
Catadromy The fact of being catadromous (see previous).
Catch The total amount of fish or other aquatic organisms landed during a certain period by the operation of fishing gear. This includes fish discarded at sea (*bycatch*), or caught by lost or abandoned gear (*ghost fishing*).
Catena A regularly recurring sequence of soil and vegetation types developed on an undulating landscape.
Cation A positively charged atom or molecule.
Cation exchange capacity (CEC) The capacity of a soil to adsorb cations such as calcium, magnesium, and potassium on the surfaces of soil particles and organic matter.
Caudal rami (singular **ramus**) In some crustaceans, a thin branching extension from the posterior segment of the body, usually paired.
CBD Convention on Biodiversity.
Cellulosic ethanol Ethanol produced by means of the conversion of cellulose, the primary structural molecule of most plants, into glucose that can then be fermented into ethanol.
Centinelan extinction The disappearance of a species before its formal recognition by science.
Cerci In insects and certain other arthropods, paired, usually unsegmented structures at the end of the abdomen, sometimes used by males during mating to grasp the female's abdomen.
Cerotegument A hydrophobic secretion layer covering the body of certain arthropods adapted to temporary submersion.
Cerrado A Brazilian term for the large areas of savanna and savanna forests that are the dominant vegetation of the Planalto of Central Brazil.
Cetacean One of the Cetacea, the order of mammals that includes the whales, dolphins, porpoises, and allies.
CFCs Chlorofluorocarbons.
Chaco A region located between the Paraná basin, the central Brazilian shield, and the Andes. Ecosystems present in the Chaco region include temperate grasslands, savannas, and arid and semiarid environments.
Chaetae (singular **chaeta**) Bristles composed of chitin cylinders held together by scleroprotein emerging from parapodia or the body wall in many annelids.
Chain-termination sequencing A method of DNA sequencing that employs four reactions, one for each nucleotide, and terminates the copy at each occurrence of a given base.
Change matrix A method of classifying land use change over a given time period, by following the exact path of change; i.e., how much land was transferred from a given use to other uses, how much came into that use, and what remained unchanged during the period.
Chaparral Evergreen sclerophyllous-leaved shrublands that cover large areas of California.
Character An attribute that is constantly distributed among all members of a species or a clade.
Character displacement Divergence in a morphological character between two species when their distributions coincide in the same ecological environment, compared to overlapping of the character when the two species are geographically separated.
Charismatic species See FLAGSHIP SPECIES.
Chela (plural **chelae**) A pincer-like claw, as in crustaceans and arachnids.
Chelate Having a pincer-like claw.
Chelicerae (singular **chelicera**) Mouth parts of the Chelicerata, a subphylum of arthropods including arachnids, horseshoe crabs, and sea spiders. They are at most three segmented appendages, usually two, and typically the distal segment acts against the penultimate to grab or hold prey or objects.
Chemical defenses Compounds used by plants to deter or poison herbivores and pathogens.
Chemoautotroph Literally, a chemical feeder; an organism able to synthesize organic compounds by the oxidation of energy-rich inorganic sources, without the use of light energy. Such an organism is **chemoautotrophic**.
Chemoautotrophy The use of energy-yielding chemical reactions as an energy source for the synthesis of organic matter from inorganic precursors.
Chemolithotroph, Chemolithotrophy See CHEMOAUTOTROPH, CHEMOAUTOTROPHY.
Chemoorganoheterotroph An organism that requires organic substrates from its environment for its for growth and development. Such an organism (e.g., herbivores, carnivores) is **chemoorganoheterotrophic**.
Chemoorganoheterotrophy A form of metabolism that relies on oxidation of organic compounds for energy, reducing equivalents, and carbon.
Chemostat An apparatus for growing microorganisms in a continually replenished medium.
Chemotroph, chemotrophy See CHEMOAUTOTROPH, CHEMOAUTOTROPHY.
Chlorofluorocarbons (CFCs) A category of hydrocarbons that are nonreactive, non-flammable organic molecules in which both chlorine and fluorine atoms replace some of the hydrogen atoms. Also known by the brand name **Freon**. Once widely used for various industrial purposes such as aerosol propellants, refrigerants, and cleaning solvents, CFCs have now been phased out because of their tendency to deplete the Earth's ozone layer.
Chondrichthyeans Sharks and their relatives.
Chordate A member of the group Chordata. This includes the most recent common ancestor of tunicates and cephalochordates and all of that ancestor's descendants. Tunicates, lancelets, hag-fishes, and vertebrates are all chordates.
Chromatin A complex of DNA and associated proteins that when assembled make up the chromosomes of eukaryotes.
Chromophore An organic molecule that absorbs photosynthetically active radiation and either carries out photochemistry or transfers excitation energy to another chromophore that carries out photochemistry. It is always bound to a polypeptide in the photosynthetic apparatus. Such a molecule is **chromophoric**.

Chromosome A long, threadlike structure in the nucleus of a cell, composed of DNA and protein.
Chronic toxicity A damaging effect caused by a long period of exposure to low or moderate concentrations of a toxin.
Chronosequence A series of sites that differ in age, but otherwise occur on similar soil types and environmental conditions within the same climatic zone.
Circannual Describing a phenomenon having a recurring cycle of approximately one year. **Circannual rhythms** recur with such a pattern.
Clade A group of organisms, such as a species, that all share a common ancestor.
Cladistic Having to do with or based on cladistics (see next).
Cladistics A method of classifying organisms based entirely on monophyletic taxonomic groupings within a phylogeny; i.e., the grouping includes all descendants of a common ancestor and no others, and taxonomic units that are paraphyletic or polyphyletic are excluded. A **cladist** is someone who practices cladistics.
Cladistic biogeography The combination of cladistics (see previous) with vicariance biogeography; a method that searches for patterns of relationship among areas of endemism.
Cladogenesis Branching evolution; the origin of diverging new forms from an ancestral lineage. Contrasted with ANAGENESIS.
Cladogram A general graphic representation of estimated cladistic relationships among taxa; it has no direct connotation of ancestry and the long axis does not connote time.
Clear-water A term for Amazonian rivers that have neither mud nor humic matter and are usually slightly acidic.
Climate change 1. Changes in global temperature, rainfall, and other aspects of climate (occurring or predicted). 2. Specifically, such a change resulting from or exacerbated by increased human production of carbon dioxide and other greenhouse gases. See also GLOBAL WARMING.
Climate sensitivity Long-term change in global mean surface temperature following an increase in carbon dioxide (CO_2) concentrations in the atmosphere, especially the significant increase since the onset of the industrial era (post-1750).
Climate teleconnections A term for the fact of climate anomalies being related to each other at large distances.
Climatic model A mathematical description of the flows of energy, momentum, and materials around the atmosphere and oceans, typically run on large computers to stimulate the Earth's climate, both naturally and when disturbed by greenhouse gases or another forcing or disturbance.
Climax (community) According to some theories of succession, the end result of succession in which successional change ends with a community that does not change and that is in equilibrium with the climate.
Clique A group of organisms in a food web in which any pair of species in the group shares at least one prey species.
Cloaca The common chamber in which the reproductive, excretory, and digestive tracts of amphibians unite before exiting the body.
Clonal 1. having to do with or being a clone (see next). 2. Specifically, describing a vegetative mode of propagation and expansion of plants by runners, tillers, or plant fragment dispersal, very important in the alpine life zone. Clonal plants also produce sexual offspring by seed, but their clonal propagules often show higher survival. All clonal offspring of one source plant have the same genome.
Clone 1. A process of producing similar populations of genetically identical individuals through asexual reproduction, as in bacteria, insects, and plants. 2. A group of individual plants formed by vegetative reproduction from a parent. The term applies particularly to those trees and plants that reproduce by creeping stems or by suckers from roots, forming circular patches of genetically identical individuals. **3**. A population of cells all descended from a single cell, or a number of copies of a single DNA fragment. 4. A process of artificially producing a multicellular organism that is genetically identical to another; e.g., a sheep or cow.
Cloning Any process in which a clone is produced, either naturally or intentionally (see previous).
Clupeid Any of various pelagic fish of the family Clupeidae, including the anchovy, sardine, and herring, which feed on plankton.
Cnidaria The marine invertebrate phylum containing the reef-building corals.
Coadapted gene complex Chromosomes, loci, or genes that are adapted to function well together.
Coalescent Looking back in time through a genealogy to a point where two genetic lineages come together in a common ancestor.
Coastal Relating to areas including estuaries, semi-enclosed seas, and shallower regions of the ocean, including areas influenced by rivers and runoff from land.
Coastal sage scrub Semiwoody shrublands dominated by drought-deciduous species, occurring in semiarid areas along the coast of southern California and the interior transition from chaparral to desert.
Coastal zone A zone whose terrestrial boundary is either the inland extent of tidal influence or the inland penetration of marine aerosols within the atmospheric boundary layer, whichever is greater. Its seaward limit is either the outer extent of the continental shelf or the limits of territorial waters, whichever is greater.
Code In nomenclature, one of the sets of internationally agreed rules governing the scientific names of organisms.
Coenosis Another term for a COMMUNITY.
Coevolution Evolved mutual adaptations between species, in which each species influences the evolution of the other.
Coevolutionary Having to do with or caused by coevolution (see previous).
Coevolutionary arms race A term for the continuing bouts of coevolving defenses and counterdefenses that occur between hosts and parasites.
Coevolve To undergo a process of coevolution (see above).
Coexistence 1. The fact of two or more species being found in the same place at the same time. 2. The ability of species to persist together in an ecological community indefinitely in the absence of any major environmental change.
Coextinction A process in which the extinction of one species leads to the loss of another species.
Cohesion The sum total of forces or systems that hold a species together; cohesion mechanisms include isolating

mechanisms in sexual species as well as stabilizing ecological selection.

Cold spot A region that is unusually lacking in a particular group of species (e.g., birds), compared with average sites in the same geographic region. Contrasted with a HOT SPOT.

Collector curve A plot of the number of species found versus the number of individuals examined. The number of species generally rises very quickly at first and then levels off toward an asymptote as fewer new species are found per unit of individuals collected.

Colonial organism A colony (see below) of single-celled organisms; postulated to be the first evolutionary step from unicellular to multicellular organisms.

Colonization The process by which a species moves into a new area where previously it was not present.

Colony A grouping of individual species of the same species living closely together; e.g., a collection of interconnected coral polyps. Often the polyps are connected with living tissue, but sometimes tissue death means that only skeletal material connects them.

Command and control A policy instrument in which regulated firms must meet individual environmental targets, often requiring the use of specific technologies. Such policies contrast with MARKET-BASED incentives, which allow firms more flexibility in meeting aggregate environmental targets.

Commensal Characterized by commensalism (see next); living in association with (e.g., on or in) another organism.

Commensalism An association of organisms in which one obtains benefit with no effect on the other. [From a term meaning "sharing a table;" i.e., sharing food.]

Commodification The act of making something a commodity (see next).

Commodity A traded item in the marketplace that is not differentiated from other similar types. An example of an agricultural commodity is Number 2 Yellow Corn, which has certain market characteristics and can be produced by many different cultivars of corn.

Common pool resource (CPR) A resource (such as an ecosystem) large enough that excluding potential beneficiaries from its use is difficult, and each individual's consumptive use (e.g., harvesting a boatload of fish or a truckload of forest products) reduces what is available to others. Also known as a **common property resource**.

Commons Resources owned in common; i.e., that are available to the public in general. Can include both public property and private property to which the public has certain rights. See also TRAGEDY OF THE COMMONS.

Community 1. An assemblage of species coexisting in a given area and interacting with each other through trophic and spatial relationships. 2. A designated subset of such an assemblage, such as the avian community or the vascular plant community.

Community structure The web of potential biological interactions among members of a community that may be characterized in terms of diversity, complexity, hierarchy, and stability.

Compact city theory The theory that more compact cities, with greater population density, are more efficient, use less energy per capita, and have less environmental impact per capita than less compact cities.

Comparative analysis Pattern-seeking across natural ecosystems, based on the premise that existing gradients and variations generate regularities that can be discerned by statistical analysis of the composite aggregate, of component variables, or of mechanistic connections.

Compensation depth The ocean depth where photosynthesis and respiration are in balance.

Competition 1. The use or defense of a resource by an individual that reduces the availability of the resource for another individual; e.g., a desirable growing site for a plant, or a food source or shelter for an animal. 2. A reduction in one species' growth rate because of the effects of another species, as by exploitation of a common resource.

Competitionism The view that competition regulates populations.

Competitive exclusion Extinction or exclusion of one species by another in a given area, through competition for resources.

Competitive release The expansion of a species-realized niche that is associated with the absence or removal of competition from other species.

Complementarity Resource partitioning among consumer species that results in greater utilization of available resources.

Complementary conservation The application of a range of conservation techniques (including *ex situ* and *in situ*) to conserve a target taxon, with one technique acting as a backup to another.

Complex adaptive system A system of multiple interconnected diverse elements whose localized interactions are subject to autonomous selection, leading to continual change and hierarchical structure.

Compositional unit A virtual subunit that contains as many types (such as species) as the actual subunits do on average, but does not share types with the other virtual subunits.

Condylarth Another term for an ARCHAIC UNGULATE.

Congener Another species that belongs to the same genus as the one being referenced.

Connectivity The linkage of habitat, land cover, or ecological processes from one location to another, or throughout an entire landscape.

Connectivity web A food web that illustrates only feeding links without reference to strength of interaction or energy flow.

Consensus cladogram or tree A branching diagram that summarizes the common branching patterns from two or more cladograms.

Conservation Active efforts by people to preserve the diversity of life on Earth and the health of natural ecosystems, usually to counteract a force that erodes or reduces natural processes. Includes the planned management of natural resources to prevent their exploitation, destruction, or neglect.

Conservation agriculture Farming practices that maintain a permanent or semi-permanent organic soil cover, such as a growing crop or a dead mulch to protect the soil physically and to feed soil biota, which improves soil quality.

Conservation biology An integrative approach to the protection and management of biological diversity that uses appropriate principles and experiences from the natural sciences, the social sciences, and various resource management fields.

Conservation concession A type of payment for ecosystem services in which a buyer purchases the right to manage a large tract of natural habitat for conservation purposes instead of commercial exploitation.

Conservation planning The process of identifying spatially explicit priorities and actions for the conservation of a region's biodiversity or natural capital.

Conservation practice or **effort** Any action taken to maintain environmental quality or to produce environmental improvements.

Conservation refugees A term for people who, as a result of the establishment of a protected area, have been displaced without fair compensation from the place where they lived, hunted, foraged, or grazed livestock.

Conservation tillage Tillage that reduces soil disruption in order to conserve organic matter and water and reduce erosion.

Conservation tourism Tourism that yields a net positive benefit for conservation of biodiversity, i.e. where contributions to conservation outweigh environmental impacts. See also ECOTOURISM.

Conserved Of a scientific name, one that the appropriate international body has decided should continue to be used for an organism in cases where a strict application of the Code would mean it had to be replaced.

Conspecific 1. Belonging to the same species. 2. An organism of the same species as another.

Constitutive defense A defense manufactured and maintained by a plant, regardless of whether it has been attacked by an herbivore or pathogen.

Consumer surplus A measure of the welfare that people gain from the consumption of goods and services, typically measured as the difference between the price that they are willing and able to pay for a good or service and the actual market price.

Contemporary (environmental) factors The current abiotic and biotic characteristics of an area, including chemical and physical aspects, as well as the composition of the biotic community.

Continental drift The movement of continents as a result of plate tectonic processes. This was especially important for Southern Hemisphere continents.

Continental rise An area at the base of the continental slope (see below) between 3000 and 4000 m, where the bottom slope is slight and sediments often accumulate.

Continental shelf A region of ocean bottom extending from the low water mark at the edge of continents to a depth (greater than 200 m) at which the incline increases markedly and the continental slope (see next) begins.

Continental slope The ocean bottom extending from the edge of the continental shelf at an average incline of greater than 4° (3000–10,000 m) at which the slope decreases and the continental rise (see above) begins.

Contour hedgerow intercropping An agricultural system in which crops are regrown in the interspaces between rows of planted woody shrub or tree species that usually are legumes, and in which the woody species are periodically pruned during the cropping season. Also called ALLEY CROPPING.

Contracted vegetation A term for vegetation restricted to wadis that receive additional water supply.

Control A process or technique of managing the population or limiting the spread of invasive species to reduce the damage they cause after becoming established in a new habitat. See also BIOLOGICAL CONTROL.

Convective mixing Vertical atmospheric mixing produced by the increasing density of a fluid in the upper layer, especially during winter in temperate and polar regions.

Convention on Biological Diversity (Biodiversity) (abbreviated **CBD**) An international convention that originated at the Earth Summit of Rio de Janeiro in 1992. Its objectives are stated as "the conservation of biological diversity, the sustainable use of its components and the fair and equitable sharing of the benefits arising out of the utilization of genetic resources, including by appropriate access to genetic resources and by appropriate transfer of relevant technologies, taking into account all rights over those resources and to technologies, and by appropriate funding." To date 193 nations have either ratified, acceded to, approved, or accepted the Convention, with the U.S. being the most prominent exception.

Convergence The evolution of similar characters in genetically unrelated or distantly related species, usually as the result of selection in response to similar environmental pressures in different places. Also, **convergent evolution**.

Conveyance The movement of water through an area. For example, by increasing the cross-sectional area available to convey flood waters, floodplains can reduce flood stage.

Cooperation See SOCIAL COOPERATION.

Cooperative breeding A social system in which more than two individuals care for young.

Coppice The regrowth of a felled tree from the stump.

Coral reef A benthic environment characterized by reef-building corals with symbiotic dinoflagellates.

Coral Triangle A name for the region, located in the waters of southeast Asia (e.g., Indonesia and the Philippines), that contains the highest diversity of corals and other marine organisms.

Core and satellite model A network of habitat patches in which centrally located core patches harbor stable populations that provide emigrants (or colonists) to ephemeral populations in satellite patches.

Core range The central part of the home range of an animal, as opposed to its outlying areas.

Correlation The process of determining the relative age of geological strata.

Corridor A linear strip of habitat connecting two otherwise isolated patches of suitable habitat, especially in a landscape altered by human activity. Corridors can be established through the conservation of existing habitat or by ecological restoration. Also, HABITAT CORRIDOR.

Cosmopolitan Being present everywhere; globally distributed.

Countryside (habitat) A landscape in which native and human-influenced habitats are combined.

Countryside biogeography A field aimed at understanding the diversity, distribution, and conservation of species in agricultural and other human-modified landscapes.

Cover (type) A term for a type of mapped land feature (e.g., forest, freshwater, or grassland).The dominant natural cover

type in a landscape is often used to approximate habitat. See also LAND COVER.

Cowbird An American blackbird in the genus *Molothrus*, which contains important brood parasites.

CPR common-pool resource.

Craniomandibular The anatomical site where the head, or cranium, and the jaw, or mandible, meet.

Crenarchaeota One of two kingdoms of organisms of the domain Archaea, including sulfur-metabolizing, extreme thermophiles. [From Greek *crene* (spring, fountain), for the resemblance of these organisms to the ancestor of the Archaea, and *archaios* (ancient).]

Crepuscular Describing organisms that are characteristically active in dim light conditions, such as at dusk or dawn.

Critical habitat A habitat required to maintain a threatened or endangered species, often itself also threatened by destruction, disturbance, or modification.

Critical load A quantitative estimate of an exposure to a pollutant below which significant harmful effects on specified elements of the environment do not occur (according to present knowledge).

Critically endangered See ENDANGERED.

Cropland Any land used for growing crops, including both sites with long-growing crops such as fruit and nut trees and those with temporary crops or temporarily fallow.

Crop mixture (mixing) An agricultural system in which two or more crop (tree) species are grown simultaneously on the same field in alternative rows or mixture, with no distinct row arrangement.

Crop rotation The practice of growing a sequence of crops in a single field over different growing seasons.

Cropping system An integrated system of agricultural production, including crop selection, management, harvest, distribution, processing, and marketing.

Crossbreeding The mating of animals of different breeds to produce commercial market animals or breeding animals. The resulting **crossbred** animals often exhibit improved fitness and performance compared to their purebred parents.

Cross-resistance The ability of a single gene or mechanism to confer resistance to more than one toxin.

Crown group A clade including a group of modern species, the common ancestor, and all its descendants, including extinct lineages.

Cryopreservation The long-term storage of gametes, embryos, or somatic cells in liquid nitrogen.

Cryoturbation A process by which soil particles and stones are moved and mixed by the frequent formation and subsequent melting of ice crystals in the soil column.

Cryptic 1. Describing an organism that is concealed or obscured by the similarity of its appearance to the surrounding environment. 2. Belonging to a cryptic species (see next).

Cryptic species Species that are virtually indistinguishable by normal morphological analysis and are, instead, defined by a combination of genetic, behavioral, and other characters.

Cryptoendolithic Living within the surface of rocks.

Cryptogam A plant that reproduces by spores or gametes rather than seeds; this includes bryophytes and lichens.

Ctenidia (singular **ctenidium**) The molluskan gill, comprising a characteristic muscular axis from which multiple filaments arise. The relative placement of ciliary bands, nerves, muscles, and blood spaces is similar in all extant taxa.

Cuckoo One of a family of birds, the Cuculidae, of which approximately half the known species (61 of 125) are obligate interspecific brood parasites.

Cultivar A cultivated variety or genetic strain of a domesticated food plant.

Cultivated plants A collective term for plants that are grown for their produce.

Cultural diversity The variation of human groups distinguished through such features as beliefs, lifeways, dress, food, languages, sexual behavior, forms of productive organization, art, and conceptions of nature.

Cultural ecology The study of how culture influences the interactions between a human population and the ecosystems in which they reside. Also, ECOLOGICAL ANTHROPOLOGY.

Cultural ecosystem An ecosystem produced by the long-term interaction of wild plants and animals with human activities.

Cultural eutrophication The acceleration of nutrient over-enrichment caused by humans; can result from direct, point-source pollution (sewers) or by diffuse, nonpoint-source pollution (such as fertilizer runoff from farm fields).

Cultural services Ecosystem services (see) that satisfy cultural needs, such as recreational, religious, spiritual, or artistic experiences.

Culture The system of socially learned, shared, and patterned ideas, institutions, behaviors, and material products that distinguishes a particular society.

Cursorial Adapted for running.

Cuticle A noncellular external layer of the body wall of various invertebrates.

Cyanobacteria A division of microorganisms that are related to the bacteria but are capable of photosynthesis. They are prokaryotic and represent the earliest known form of life on Earth. Formerly known as BLUE–GREEN ALGAE.

Cyanophage A virus that infects cyanobacteria.

Cyanotoxin A group of toxins produced by various freshwater, marine, and terrestrial cyanobacteria.

Cycadeoidales Another name for the BENNETTITALES.

Cyperaceae The formal name of the sedge family of plants.

Cytochrome P-450 monooxygenases A ubiquitous group of enzymes involved in the NAPDH-mediated oxidation and metabolism of a broad range of endogenous and exogenous substrates.

Cytotoxicity The ability of a chemical compound to kill cells in an experimental system, such as a petri dish. Such a compound is **cytotoxic**.

Damage costs Costs associated with damages to economic activities arising from conservation programs; e.g., damage to crops and livestock from wild animals living in protected areas adjacent to human settlements or direct wildlife attacks on humans.

DDP Dryland Development Paradigm.

Decomposer An organism that acts to break down dead or decaying plants and animals; e.g., bacteria, fungi, worms.

Decomposition The breakdown of organic matter such as dead plants and algae to release carbon and nutrients.

Deep ecology An activist philosophy that advocates significant personal and political change to protect the natural environment.

Deep sea 1. Volumes of water or areas of ocean bottom at depths greater than 200 m. 2. **deep-sea**. Having to do with this area.

Definitive host For parasites with complex life cycles, the host in which the parasite reproduces sexually. Also, FINAL or PRIMARY HOST.

Deforestation The most intense form of timber extraction, in which forests are converted for another land use such as agriculture or ranching, either permanently or for a long term. Can be specifically defined as depletion of forest crown cover to less than 10 percent density.

Degradation A temporary or permanent loss of ecosystem structure, productivity, and native species diversity. Directly related to declines in biodiversity, degradation encompasses soil impoverishment and hydrological alterations that diminish water availability. See also DESERTIFICATION.

Degraded 1. Having undergone a process of degradation (see previous). 2. Specifically, describing agricultural land in which the productivity has been reduced as a result of human actions.

Delphinidae The family of odontocete cetaceans that includes the dolphins. Delphinids are the most diverse family of marine mammals, with 36 species currently recognized, more than one quarter of the known modern species of marine mammals.

Deme A localized breeding group or subpopulation, often confined to a single habitat patch.

Dendrogram A branching, nonreticulate diagram expressing nested hierarchical relationships or similarities (or both) between entities (e.g., taxa), such that the entities only appear at the tips of terminal branches.

Denitrification The reduction by bacteria of nitrate or nitrite to gaseous nitrogen products, mainly N_2 and N_2O.

Density dependence The condition that environmental factors influence population growth rate in relation to population size. Density dependence usually is seen as a linear, inverse relationship between population growth rate and population density (i.e., population growth decreases as density increases) and may occur if individuals compete or predators are more effective as a prey population increases.

Density independence The absence of environmental factors that influence population growth as a function of density. This may occur if mortality removes a fixed percentage of a population, independent of population size.

Denticles Small tooth-like projections such as those that occur on shark skin.

Depauperate Of low diversity; lacking in species richness. Contrasted with SPECIOSE.

Depletion 1. The near or total exhaustion of a resource through human overexploitation. 2. Specifically, a reduction in population of a fishery to a level low enough to reduce or threaten future productivity. **3**. See OZONE DEPLETION.

Deposit feeder An organism that feeds primarily by ingesting organic material occurring on or between sediment grains.

Deposition 1. The delivery of material inputs to the Earth's surface from the atmosphere. 2. The rate of influx of a substance in this manner, usually expressed as mass per unit area of ground.

Derived 1. Describing a trait or condition that appears in a descendant species and is changed from the ancestral condition. 2. Describing taxa with such traits or conditions.

Desertification Reduction of the biological potential of land that ultimately leads to the creation of desert-like conditions, through factors such as a decline in primary productivity, elimination of biological cover, shifts in plant diversity, or degradation of soils. Can result from natural climatic variation but usually occurs primarily through overexploitation of marginal lands by humans for agriculture; e.g., overgrazing by livestock.

Desertification myth The argument that the popular conception of African deserts expanding inexorably across fertile lands exaggerates the extent to which this process is happening, and overemphasizes the role of human activity in the process.

Desmostylia The only known fully extinct order of marine mammals, closely related to the sirenians. Desmostylians were large herbivorous quadripedal animals living in shallow waters during Oligocene and Miocene times, possibly resembling the modern hippopotamus in ecology, behavior, and appearance. They are known in the fossil record only from coastal regions of Oregon and Washington State.

Detoxification 1. A lessening of the toxic properties of some substance. 2. Specifically, a reduction in the toxic effect of a pollutant by its chemical or biological transformation to another less toxic chemical.

Detrital shunt A process in which energy and nutrients from the saprotrophic (detritus-eating) web re-enter the plant herbivore predator food web when detritivores are eaten by predators that also eat plants, herbivores, or other predators.

Detritivore An organism that consumes dead plant or animal material. Such an organism is **detritivorous**.

Detritus Dead organic matter, in either soluble or particulate form.

Diapause A state of dormancy in some animals that is induced by a so-called token environmental cue, such as day length. The token cue serves as a reliable indicator of a coming onset of harsh environmental conditions, but is not by itself harsh.

Diaspore A plant part distributed by dispersal, regardless of its developmental and morphological origins. It may be a naked seed, a seed enclosed in a fruit, or many seeds enclosed in a fruit, also a bulb or length of rhizome.

Diastema A large gap between incisors and premolars that is thought to allow an animal enough space to manipulate food with the tongue.

Diazotrophs Free-living or symbiotic bacteria or archaea that are capable of reducing N_2 to a biologically utilizable form of nitrogen (N) or ammonia (NH_3).

Dichotomous tree A cladogram in which all nodes are bifurcate (split into two parts).

Dichotomy Two taxa arising from one node.

Diffused vegetation A term for vegetation occupying all slopes and most habitats.

Digitigrade 1. Literally, walking on the digits; a posture where the majority of the weight is borne by the metacarpal and metatarsal bones and the heel/palm is raised off the

ground. 2. An organism that walks in this manner; e.g., dogs, cats, and various other mammals, or walking birds. Compare PLANTIGRADE, UNGULIGRADE.

Dilution effect The phenomenon by which increases in biodiversity are associated with decreases in the transmission, risk, or incidence of infectious disease.

Dilution host A species that reduces rates of transmission of pathogens.

Dinitrogen N_2; the most abundant form of nitrogen (N) in the atmosphere.

Dioecious Describing plants that have the male and female reproductive organs borne on separate individuals of the same species.

Diploid 1. Describing an individual with two sets of chromosomes, usually received from different parents, in contrast with a HAPLOID organism such as most microorganisms, the gametophyte stage of higher plants and some parthenogenetic forms (e.g., male ants and honeybees). 2. An organism of this type. It may have the same form or allele of a gene on both members of a chromosome pair, in which case it is *homozygous*, or in different forms (alleles), in which case it is *heterozygous*.

Diptera The group of insects to which the flies belong, including gnats and mosquitoes.

Dipterocarp A member of the Dipterocarpaceae family (comprising 22 genera) of South Asian and African timber trees.

Direct land-use change (DLUC) Conversion of land from a non-crop use to the production of bioenergy crops.

Direct use values Benefits gained from environmental goods and services that involve some form of direct physical interaction, such as recreational activities, resource harvesting, drinking clean water, breathing unpolluted air, and so on. Compare INDIRECT USE VALUES.

Disease Infection by parasitic organisms that can cause weakness, decreased reproduction, and death.

Disease dynamics Changes in incidence or prevalence of disease through time.

Disease incidence The number of new cases of a disease per population per unit time, often expressed as a rate.

Disease prevalence The number of disease cases per population.

Disharmonic Describing a fauna in which a strongly reduced number of major lineages is represented, as in oceanic islands, due to their improbable colonization from distant sources.

Disharmony The non-random representation of biota among natural colonists of oceanic islands as compared with mainland systems. Species that are more dispersive will have a higher representation in the biota, the effect being accentuated by the tendency of these few successful colonists to diversify in to multiple species through adaptive radiation.

Disparity The range of diverse morphological architectures present in higher taxa such as classes, phyla, and kingdoms; used to explain the origins and maintenance of this diversity of life-forms and body plans.

Dispersal 1. Any movement or spread of an organism from one area to another independent of other organisms and of historical events that change the natural distribution of the organism. 2. The movement of an individual organism away from its place of origin to the place where it breeds, or the movement by an adult from one breeding location to another.

Dispersal limitation The degree to which the location of an organism is constrained by the location of its parent; the inability to move to and colonize another location.

Disruptive selection Selection acting to preserve extreme phenotypes in a population. Speciation usually involves disruptive selection, because intermediates (hybrids between incipient species) are disfavored. Compare STABILIZING SELECTION.

Disruptor See ENDOCRINE DISRUPTOR.

Dissipative beach A wide, flat beach.

Distance–decay A decrease in the similarity of community composition with increasing spatial distance.

Distinct (population) segment A subspecific unit that can be afforded legal protection under the U.S. Endangered Species Act.

Disturbance Any relatively discrete event that disrupts ecosystem, community, or population structure and changes resources, substrate availability, or the physical environment, particularly one that results in increased mortality of plants or animals. Disturbances may be natural events such as wildfires, hurricanes, tornados, or landslides, or human effects such as logging or land clearing.

Disturbance regime The collective spatial, temporal, physical, and ecological characteristics of a disturbance process operating in an area.

Divergence 1. A fixed genetic difference between two species or populations. 2. The process of evolving such a difference.

Divergence-with-gene-flow A model explaining the process of species formation (speciation) in which new species diverge in the face of gene flow; i.e., the movement of genes within a group that results from mating with immigrant individuals.

Diversity A quantitative measure of the taxonomic or physiognomic composition of coexisting organisms at one of three scales: *alpha* (local diversity), *beta* (diversity change between adjacent local sites), and *gamma* (regional diversity). See also BIODIVERSITY.

Diversity index A numerical measure combining information about the diversity of species present in a sample or habitat and information about their relative abundances.

Diversity principle The principle that there is a general geographical coincidence between high concentrations of biological diversity and cultural diversity.

Diversity-productivity hypothesis The proposal that greater diversity would lead, on average, to greater total biomass or productivity.

Diversity-stability hypothesis The proposal that ecosystems containing more species would be more stable.

DLUC Direct land-use change.

DNA Deoxyribonucleic acid, the crucial molecule of inheritance that stores genetic information passed from one cell to another and from one generation to succeeding generations, composed of four nucleotides: adenine (A), cytosine (C), guanine (G), and thymine (T).

DNA barcoding A method of delimiting species by means of the clustering of short stretches of DNA sequence data called "barcodes," usually from mitochondrial DNA.

DNA fingerprinting A technique used to amplify small amounts of DNA to identify individuals, often for forensic purposes.

DNA probe array A collection of short, single-stranded, uniquely addressable segments of DNA attached to a solid surface; used to detect the presence or expression of specific genes via the principles of nucleic acid hybridization. A **protein probe array** is similar but with proteins serving as sensing elements.
DNA slippage A polymerase error leading to a change in the length of a simple repetitive sequence.
Dodder Viney parasitic plants of the genus *Cuscuta* that form haustoria (specialized nutrient absorbing structures) on the stems of their hosts. The unrelated parasitic vine, *Cassytha*, is often referred to as Laurel Dodder.
Domain The highest level of taxonomic rank used to classify organisms; the three domains are Archaea, Bacteria, and Eukarya, which differ from each other in fundamental genomic and phenetic properties.
Domesticate 1. To purposely adapt an animal or plant from a wild to a controlled state for some human use. The process of doing this is **domestication**. 2. An animal or plant that has been adapted in this way.
Dominant (species) 1. Species that have the greatest influence on ecosystem structure and function, by virtue of their high abundance, biomass, and/or coverage. Examples include trees in forests, grasses in grasslands, mussels in rocky intertidal habitats, and kelp or coral in near-shore subtidal habitats. 2. Having to do with or being such a species.
Donor control A condition in a food web in which consumer population growth is affected by their resources but consumers do not affect the renewal rate of these resources and hence cannot depress them.
Dormancy Any state of reduced metabolic activity of an organism. Typically, dormant organisms have associated characteristics such as cessation of development, absence of reproduction, and enhanced resistance to harsh environmental conditions.
Dormant In a state of dormancy (see previous).
Dorsal The part of an organism that is the "back" or upper part of the body. Contrasted with VENTRAL which is the "front" or lower part.
Drift The influence of stochastic demographic variability (such as birth, death, and migration rates) on biotic composition in an area.
Drought-deciduous Describing plant species that lose their leaves during the dry season as soil moisture becomes limited.
Dryland Development Paradigm (DDP) A conceptual framework to aid in understanding the complexity of desertification and dryland development, by identifying and synthesizing the factors important to the research, management, and policy communities.
Drylands A collective term for arid and semiarid croplands, pastures, rangelands, and subhumid woodlands where the index of aridity is less than 0.65; these cover more than two-fifths of the land surface of the globe, and are home to more than one-third of the human population.
Dyke intrusion Magma that upwells from the mantle; may reach the surface of the Earth's crust to flow out as lava and solidify as basalt.
Dynamical model A mathematical description of a system with components that vary in time.
Dynamical system A set of rules defining how certain variables change with time. Ecological models are dynamical systems representing what are believed to be vastly more complex dynamical systems in nature.
Dynamical variable A quantity in a dynamical system that changes with time according to the rules of the system.
EBM Ecosystem-based management.
Ecoagriculture A land-use approach that achieves agricultural production and sustains rural livelihoods, in ways that also protect wild plant and animal species and the natural ecosystem services upon which both humans and wildlife depend.
Ecocriticism The interdisciplinary study of literature, history, religion, and philosophy with an emphasis on habitats, evolutionary biology, and environmental problems.
Ecogeography The analysis of a species' ecological, geographical, and taxonomic characteristics to assist in the formulation of collection and conservation priorities.
Ecohumanism See HUMANISM.
Ecological 1. Having to do with ecology, the study of the relationship of organisms to each other and their environment. 2. Having to do with the natural environment, especially its protection and sustainable use.
Ecological anthropology See CULTURAL ECOLOGY.
Ecological biodiversity See BIODIVERSITY.
Ecological biogeography See BIOGEOGRAPHY.
Ecological community See COMMUNITY.
Ecological footprint The "mark" that people leave on the natural environment; a quantitative calculation to estimate the cumulative environmental impact of a human individual or population, especially in the context of daily activities. See also CARBON FOOTPRINT.
Ecological function See ECOSYSTEM FUNCTION.
Ecological integrity The balanced state of an ecosystem under normal environmental conditions, including its capacity to absorb disruption and also to recover from it.
Ecological niche See NICHE.
Ecological process 1. Any of the direct or indirect interactions between species, such as grazing, predation, competition, responses to disturbance, and so on, that cause spatial or temporal patterns in the distribution and abundance of the species. 2. See ECOSYSTEM PROCESS.
Ecological refugee A term for people who have lost access to their traditional base of natural resources yet have very limited access to resources through markets.
Ecological release The expansion of habitat, or ecological environment, often resulting from release of species from competition.
Ecological restoration See RESTORATION.
Ecological sorting The process by which organisms colonize and persist in novel environments, use novel resources, or form novel associations with other species, as a result of the suite of traits that they carry at the time they encounter the new condition. This provides an important mechanism by which new species can fit in to an existing community without adaptation.
Ecological stoichiometry The quantitative relationship between chemical elements (especially carbon, nitrogen, and phosphorus) arising from ecological processes and interactions such as nutrient acquisition, biomass formation,

remineralization, trophic transfer, sedimentation, and dilution.

Ecological transfer efficiency The ratio of energy ingested by a population's predators to the energy ingested by the population itself.

Ecological transition The concept that human societies tend to be in growing disequilibrium with their biophysical environment as they increasingly deplete natural resources and degrade their habitat, thus reaching new levels of environmental impact.

Ecologist A scientist who studies the relationship of organisms to each other and their environment.

Ecology The scientific study of the relationships of organisms with each other and with their environment, at levels ranging from the interaction of two individual organisms to the entire biosphere; it includes issues such as the nature, distribution, abundance, and diversity of species, the flow of energy and materials, and the effects of human activity on natural systems.

Ecomorph A local population or group associated with a particular ecological niche.

Economic botany The scientific effort to identify and characterize economically useful plants and the products derived from them.

Economic efficiency Another term for PARETO EFFICIENCY; i.e., an equilibrium condition in which all goods in an economy are allocated in such a way that no one can be made better off without making someone else worse off.

Economic rent The flow of net economic benefits (revenue minus costs) derived from the exploitation of a resource asset.

Economic value (valuation) In this context, the various methods used by economists to determine the willingness of individuals to pay for the benefits they derived from ecosystems, many of which are not marketed.

Ecoregion A relatively large unit of land or water containing a distinct assemblage of natural communities that share a large majority of their species and ecological dynamics, and also share similar environmental conditions, and interact ecologically in ways that are critical for their long-term persistence.

Ecospecies A species considered in the context of its ecological characteristics and usually including several ecotypes (see) that are capable of interbreeding.

Ecosystem A community of organisms (plants, animals, and microbes) and their physical environment (air, soil, water, and so on) interacting as an ecological unit in some defined geographical space, such as a lake, a wetland, a forest, or an agricultural landscape.

Ecosystem approach A strategy for the integrated management of land, water, and living resources that promotes conservation and sustainable use in an equitable manner.

Ecosystem-based adaptation Conservation and management of natural ecosystems so that they can provide services to help society adapt to perturbations from climate change.

Ecosystem-based management (EBM) An environmental management approach that recognizes the full array of interactions within an ecosystem, including humans, rather than considering single issues, species, or ecosystem services in isolation.

Ecosystem disservices The converse of ecosystem services (see); functions or processes provided by ecosystems that have a negative impact on people; e.g., disease agents, agricultural pests.

Ecosystem diversity See BIODIVERSITY.

Ecosystem engineer A species that directly or indirectly modulates the availability of resources (other than itself to other species) by causing physical state changes in biotic or abiotic material and in so doing modifying, maintaining, or creating habitats. Examples are animals that affect an ecosystem by physically changing it (such as beavers building dams) or by being present in such great numbers that they have a disproportionate impact (such as large grazing animals). Also applied to organisms that move parts of the soil volume for their own use (such as earthworms making macropores that permit the flow of large amounts of water through the soil). Also, **ecosystem engineer species**.

Ecosystem function(ing) Any of the physical, chemical, and biological processes or attributes that contribute to the self-maintenance of an ecosystem (e.g., nutrient cycling, primary production, food web systems).

Ecosystem goods Commodities, such as timber and seafood, supplied free to humanity by natural ecosystems.

Ecosystem health The condition of an ecosystem, whether natural, managed, or human-dominated, that is free from influences that would damage or destroy its characteristic structures and functions.

Ecosystem integrity See ECOLOGICAL INTEGRITY.

Ecosystem management The management of an ecologically defined geographical area as an integrated whole for both sustainable yields of natural resources and maintenance of ecological processes and species populations.

Ecosystem people A description for people who directly meet the bulk of their resource requirements from a limited area near their habitation, as through gathering or low input agriculture and animal husbandry.

Ecosystem process Another term for ECOSYSTEM FUNCTION.

Ecosystem resilience See RESILIENCE.

Ecosystem services A broad term for the many and varied benefits that people obtain from natural ecosystems. These include *provisioning* services such as food and water; *regulating* services such as flood and disease control; *cultural* services such as aesthetic and recreational benefits and spiritual values; and *supporting* services, such as nutrient cycling, which maintain the conditions for life on Earth.

Ecosystem structure The sum of the biotic (living) and abiotic (nonliving) components of an ecosystem, and the interactions among them.

Ecotonal Having to do with or occurring in an ecotone (see next).

Ecotone A zone or transition between adjacent ecological systems, having a set of characteristics uniquely defined by space and time scales, and by the strength of the interactions between adjacent ecological systems.

Ecotone effect The pattern of increased species richness (number of species) and abundance in ecotones and the occurrence of unique ecotonal species.

Ecotourism Commercial tourism that focuses on relatively undisturbed natural environments, and that takes steps to minimize environmental impacts, provide environmental education to clients, and contribute to environmental conservation.

Ecotoxicology The use of test organisms (e.g., the water flea, *Daphnia*) to study the toxicity, pathways of accumulation, and breakdown of chemicals, particularly those manufactured by humans (e.g., pesticides).

Ecotype A genetically different type within a species that reflects an obvious advantage in a given environment. Ecotypic traits are retained when individuals are transplanted into a different environment where these traits have no advantage.

Ecotypic Having to do with or being an ecotype (see previous).

Ecozone A major division of the Earth's land surface, based on the general groupings of the organisms found there.

Ectoderm An embryonic tissue that provides the future outside layer of the animal.

Ectoparasite A parasite living on the surface of a host.

Ectotherm An animal whose body temperature has minimal internal regulation and instead varies with external conditions; e.g., snakes.

Ectothermic Describing animals whose body temperature is regulated mainly by the exchange of heat with the surrounding environment; in popular use, "cold-blooded."

Ectothermy A method of body temperature control in which the animal utilizes the Sun and other external sources for gaining and giving up heat, thus achieving temperature control without affecting metabolic rate. Contrasted with ENDOTHERMY.

Edaphic Related to or caused by particular soil conditions, as of texture or drainage, rather than by physiographic or climatic factors.

Edge effect The effect of the juxtaposition of contrasting environments on an ecosystem.

Edge-of-field loss A term for the nitrogen and phosphorus that is lost or exported from fields in agricultural production.

Effective population size (Ne) The size of an ideal population that would have the same rate of increase in inbreeding or decrease in genetic diversity as the actual population under study.

Effective species A virtual species that has the same proportional abundance as the actual species do on average. The number of effective species, or effective number of species, is species diversity.

Efficiency 1. The degree of success in reaching a conservation goal (e.g., maximizing the number of species in a given area) relative to the cost (or to some surrogate for cost, such as number of areas). 2. A condition of economic equilibrium. See PARETO EFFICIENCY; KALDOR-HICKS EFFICIENCY.

Efficiency frontier A condition where it is not possible to improve on any particular objective without decreasing some other objective; can be used to determine the maximum feasible outcome that can be achieved for a landscape.

Effluent line The level on a beach face where the water table intersects the surface.

Egg bank An accumulation of long-lived diapausing eggs (i.e., those eggs that persist in diapauses for longer than a single growing season) of aquatic invertebrates in the sediments of marine or freshwater habitats.

Egg rejection Host responses to parasitism that include the ejection of parasitic eggs, abandonment of parasitized nests (usually with renesting), or a new cup built over a parasitized clutch. See also MAFIA EFFECT.

EIA Environmental impact assessment.

EID Emerging infectious disease.

El Niño Southern Oscillation (ENSO) A periodic climate pattern that takes place across the tropical Pacific Ocean at intervals of approximately five years, characterized by warmer than normal ocean surface temperature and greater air surface pressure in the eastern and western tropical Pacific Oceans, respectively. The other phase of the cycle, the **La Niña Southern Oscillation**, is characterized by colder than normal surface waters and lower air surface pressure. ENSO events are associated with changes in rainfall patterns in the tropics and with an influence on the weather at higher latitudes, and also with changes in fisheries and ecosystem processes. [From Spanish *El Niño*, the male child (i.e., the Christ child); based on a traditional name for warmer ocean currents occurring around Christmastime.]

Electrophoresis The separation of charged molecules (such as polypeptides or polynucleotides) between the two poles of an electric field.

Elemental stoichiometry See ECOLOGICAL STOICHIOMETRY.

Elfin woodland Small, stunted tree growth characteristic of forests at higher elevations in warm, moist regions.

Elite capture The argument that benefits from a conservation or a development initiative may be "captured" by local elites who have the economic or political power to determine who will benefit from such an initiative.

Eltonian niche The role, or occupation, of a species in a community, likened to the way a person's profession establishes their role in the community. [Conceived by the British ecologist Charles Elton.]

Eluviation The process in which dissolved or suspended materials in soil move from a higher to a lower level.

Emergent Describing vegetation rising above a certain level or surface; e.g., a very tall tree that rises above the general level of the forest canopy, or a plant that grows in water but rises partially above the surface; e.g., cattails.

Emerging infectious disease (EID) A disease of infectious origin whose incidence in humans has recently increased and may continue to increase in the near future; it may be a newly recognized disease or a **re-emerging** disease that was previously recognized. EIDs are associated with various causal factors such as changes in land use or human-wildlife interactions, or climate change (e.g., spread of West Nile virus).

Enchytraeid One of the Enchytraeidae, segmented worms that are related to but smaller than earthworms.

Endangered Facing a very high risk of extinction in the wild, based on specific criteria. In some systems that classify extinction risk, *endangered* is the highest category of risk, followed by *threatened*. In others it is second highest after *critically endangered*.

Endangered species A species that is at substantial risk of extinction throughout all or a significant portion of its range.

Endemic 1. Describing a species or other taxonomic group that is restricted to or occurs only in a specified geographic location or region. The actual size of the area is arbitrary (an **endemic species** might be found only in North America or only on a small island). 2. A member of such a species or group.

Endemic language One of the languages that are restricted to a single country and, like their species counterparts, hold a high percentage of the unique traits in human language as a whole.

Endemism The fact of a species or other taxonomic group being found only in a specific location of limited size, rather than being widely distributed. Also, **endemicity**.

Endocrine disruptor A chemical that interferes with the endocrine system, the means of chemical communication (mainly performed by hormones) within an organism.

Endogenous 1. Inside; occuring within a system. 2. Specifically, occurring within an organism or a population of organisms. Contrasted with EXOGENOUS.

Endogenous forces Forces within a population that affect the dynamics of the population.

Endogenous process A process that emerges from biotic and abiotic interactions internal to the system of interest. Examples include vegetation growth and succession, dispersal of organisms within a landscape, and topographic influences on microclimate. Some human activities may be considered endogenous (e.g., crop rotation systems) if they are well established and responsive to local needs.

Endogenous risk The concept that private citizens and public servants have some control over the set of probabilities and outcomes that define the relevant states of the world.

Endoparasite A parasite living inside a host.

Endophyte 1. A fungus or other parasitic organism residing or growing within plant tissue. Such an organism is **endophytic**. 2. The portion of such an organism that is embedded inside the host tissue.

Endosperm Nutritive storage tissue in the seeds of most angiosperms.

Endosymbiont An organism living in a long-term association inside a host organism for their mutual benefit; e.g., methanogenic bacteria that live inside an aerobic protozoa and utilize waste H_2 produced by the host). Such an association is **endosymbiotic**.

Endotherm An animal whose body temperature is mainly regulated by its own metabolism and varies only slightly with external conditions; e.g., mammals.

Endothermic Describing animals who regulate their body temperature mainly through internal metabolic means; in popular use, "warm-blooded."

Endothermy A method of body temperature control in which the animal modifies its metabolic rate to achieve the desired temperature, largely independent of the ambient temperature. Contrasted with ECTOTHERMY.

Enemy release hypothesis The idea that alien species have a better chance of establishing and becoming dominant when released from the negative effects of natural enemies that, in their native range, lead to high mortality rates and reduced productivity.

Energetic web A food web depiction that quantifies the amount of energy (or material) that flows across the links joining species.

Energy 1. A fundamental physical concept, defined classically as the capacity to perform work. **Potential energy** is this capacity stored as a consequence of its position, structure, shape, or state. **Kinetic energy** is this capacity as manifested in the motion of matter. The joule (J) is the common SI unit of energy, where 1 J equals the amount of energy required to increase the temperature of 1 g of water by 1° K. 2. The use of this capacity by humans to perform useful functions, such as heating or cooling, lighting, transportation, powering devices and tools, and so on. See also RENEWABLE ENERGY; NON-RENEWABLE ENERGY; INDUSTRIAL ENERGY; TRADITIONAL ENERGY.

Energy balance 1. The difference between incoming solar energy and outgoing terrestrial radiation for the Earth as a whole. 2. The relative energy flows into and out of a living system, such as an ecosystem or an individual organism. Also, **energy budget**.

Energy efficiency A measure of the performance of an energy system. **First Law efficiency** (based on the first law of thermodynamics) equals the ratio of desired energy output to the energy input. **Second Law efficiency** (based on the second law) equals the ratio of the heat or work usefully transferred by a system to the maximum possible heat or work usefully transferable by any system using the same energy input.

Energy sprawl An increase in the agricultural land area required for the production of dedicated biofuel crops in place of food crops, natural and semi-natural habitats, and other land uses, occurring directly from land-use change or indirectly due to biofuel-related market conditions.

Engineer See ECOSYSTEM ENGINEER.

ENSO El Niño Southern Oscillation.

Entropy A measure of the degree of disorder, or randomness, in a given system at a given time; greater entropy means less energy available to do work. The entropy of an isolated system cannot decrease when the system undergoes a change.

Environment 1. The entirety of the biological world and its physical surroundings. 2. The living and non-living surroundings of a particular organism.

Environmental 1. Relating to the natural environment and the impact of human activity on it. 2. Describing efforts to protect the viability and diversity of the natural world.

Environmental ethics The philosophical discipline that describes and specifies proper human relationships with the natural world.

Environmental filter(ing) Constraints on the presence and abundance of species in local communities or regional species pools, due to abiotic conditions.

Environmental impact assessment (EIA) A formalized process, including public consultation, in which all relevant environmental consequences of a project are identified and assessed before authorization is given to proceed.

Environmental Kuznets curve See KUZNETS CURVE.

Environmental stress An action, agent, or condition that impairs the structure or function of a biological system.

Environmental sustainability 1. The fact of maintaining ecosystem conditions that will sustain the biosphere now and into the future. 2. The complex of environmental, economic, social, and cultural systems necessary to accomplish this.

Environmental variables The abiotic and biotic elements of an area including vegetation, soil, topography, species competition, geology, prevalence of diseases and hydrologic characteristics, among others. Habitat selection can be positively or negatively related to these environmental variables.
Enzyme A protein involved in catalytic reactions.
Eolian Another spelling of AEOLIAN.
Epigenetic Having to do with molecules that are the product of gene expression.
Epikarst 1. The interface zone between soil and rock, characterized by fractures and small solution pockets. 2. An ecotone between surface and subterranean water in karst.
Epiphyl A plant that grows on the leaf surface of another plant.
Epiphyte A non-parasitic plant that uses another plant, usually a tree, as mechanical support but does not derive nutrients or water from it. Such a plant is **epiphytic**.
Epiphytic material Live and dead canopy vascular and nonvascular plants, associated detritus, microbes, invertebrates, fungi, and crown humus.
Epistasis An interaction between different alleles at two or more loci, such that the phenotype differs from what would be expected if each locus acted independently.
Equalizing mechanisms Biotic or abiotic forces giving rise to equal net per-capita population growth rates of individuals of different species in a community.
Equity See SOCIAL EQUITY.
Eremic Relating to or occurring in desert regions.
ESS Evolutionarily stable strategy.
Estuary A semi-enclosed coastal body of water that has a free connection with the open sea and within which the water is brackish; i.e., it has a moderate level of salinity due to the seawater being diluted by fresh water from land drainage.
Ethical holism The principle that complex aggregates have intrinsic value, such as species, ecosystems, or human groups.
Ethics Codes that exert a palpable influence on human behavior. Embedded in world views, ethics provide models to emulate, goals to strive for, and norms by which to evaluate actual behavior.
Ethnobiology 1. The study of the reciprocal interactions between people and the biological organisms in their local environment. 2. The study of the ways in which different cultures interact with and make use of the organisms in their environment, both in the present and the past. Ethnobiology can be divided into **ethnobotany** with respect to human interaction with plants and **ethnozoology** with respect to animals.
Ethnobotany See ETHNOBIOLOGY (previous).
Ethnoecology An interdisciplinary study that explores how nature is perceived by human groups and how humans use natural resources. May focus specifically on the traditional environmental knowledge and practices of local groups, as exemplified by their resource management.
Ethnoscience The study of local peoples' knowledge of biological organisms and the physical environment, especially their systems of classification and naming. See also ETHNOBIOLOGY.
Ethnozoology See ETHNOBIOLOGY.
Ethology The study of the behavior and social relations of animals.
Eucalyptus A diverse genus of trees and shrubs including species that grow quickly to great height; the dominant tree genus of Australia today and also widely cultivated in tropical and subtropical areas elsewhere.
Eukarya or Eukaryota One of the three domains of life, along with the Archaea and Bacteria, consisting of the organisms that have a membrane-enclosed nucleus and other organelles. Also spelled **Eucarya**.
Eukaryote A cellular organism in which the genome of the cell is stored in chromosomes enclosed in a membrane-bound nucleus; all protists (algae and protozoa), fungi, plants, and animals are eukaryotes. Also spelled **eucaryote**. Compare PROKARYOTE.
Eukaryotic Relating to or being a eukaryote (see previous).
Euphotic Describing the top layer of a water body through which sufficient light penetrates to support net photosynthesis.
Euphotic zone The uppermost sunlit layer of the ocean, lake, or another body of water, in which there is sufficient light energy to support net photosynthetic growth. Can vary from up to about 200 m in the open sea to as little as 1 m in turbid lake waters. Also, PHOTIC ZONE.
Euryarchaeota One of two kingdoms within the domain Archaea, including halophiles, methanogens, and some anaerobic, sulfur-metabolizing, extreme thermophiles.
Eurythermal Able to tolerate a wide range of temperatures. An organism with this ability is a **eurytherm**.
Eusociality Cooperative behavior among individuals of the same species, characterized by reproductive division of labor, overlap of generations, and cooperative nesting. Such behavior is **eusocial**.
Eutherian One of the Eutheria, the mammals in which the embryo is attached to the mother by a placenta.
Eutrophic 1. Describing an ecosystem that is high in production, or a species typical of high-production environments. 2. Specifically, describing an aquatic ecosystem characterized by high phytoplankton production and high nutrient concentrations and loadings. Compare MESOTROPHIC; OLIGOTROPHIC.
Eutrophication 1. The fact of an ecosystem being or becoming high in production. 2. Specifically, the process by which a lake or other aquatic environment becomes enriched with nutrients such as nitrogen; this stimulates plant growth and often leads to losses of plant biodiversity with dominance by algal species, and the depletion of oxygen from the water. Also, **eutrophy**.
Evaporative aerodynamics The study of the influence of aerodynamics on the development of both leaf structure and foliage distribution throughout a plant community.
Evapotranspiration The process of transferring moisture from the earth to the atmosphere by the evaporation of water and transpiration from plants.
Evenness An equitable condition in the abundance of the species present in a local community or region.
Evolution Descent with modification; morphological or genetic change in species over time. Small changes that do not lead to reproductive isolation among members of a group are referred to as *microevolution*. Speciation, or the generation of new species, is referred to as *macroevolution*.

Evolutionarily stable strategy (ESS) An optimal strategy that, if adopted by all the members of a population, can resist invasion by any new (mutant) strategy; i.e., it is stable with respect to evolutionary change.
Evolutionary equilibrium The hypothesis that frequencies of acceptance of brood parasitism reflect an equilibrium between costs and benefits of host defenses against parasitism.
Evolutionary lag The hypothesis that hosts lack defenses against brood parasites because the defenses have not yet had time to evolve.
Evolutionary legacy Genetic resources that are the product of past evolutionary events and also represent the raw material for future evolution.
Exaptation A process in which a trait first evolves to serve one particular function, but subsequently comes to serve another.
Existence value The benefit derived simply from knowing that something exists, without making use of it; e.g., a certain natural ecosystem.
Exoenzymes Digestive enzymes excreted by fungi into the environment to digest materials externally.
Exogamy Reproduction in which the individuals are not closely related to each other. Such a reproductive pattern is **exogamous**.
Exogenous 1. Outside; occuring outside a system. 2. Specifically, occurring outside an organism or a population of organisms. Contrasted with ENDOGENOUS.
Exogenous forces Those forces outside a population that affect the dynamics of the population.
Exogenous process A process external to the system of interest. For landscapes, exogenous processes would include climate change or species migration into the landscape. Human activities may be considered exogenous if they are novel, permanent (e.g. a housing development), or driven by external forces (e.g., the world market for timber).
Exons Parts of a gene sequence transcribed and translated into a protein; usually interrupted by *introns* which are spliced out of messenger RNA before translation.
Exotic Occurring in an area outside of its historically known range; not native or indigenous.
Exotic animal 1. A wild animal; i.e., an animal that has not been domesticated for use by humans in agriculture or as a pet. 2. A member of an exotic species (see next).
Exotic species A species occurring outside its natural range or potential natural dispersal range, especially one whose presence there is due directly or indirectly to human activity.
Exploitation Any use of a natural resource or other ecosystem service by humans. See also OVEREXPLOITATION.
Exploitation (exploitative) competition Interaction among two or more species that use a common resource that is limited, in which one species benefits more than the other.
Ex situ Literally, "outside its position;" not in its natural setting (*in situ*), but rather in a laboratory, zoo, or other such artificial setting.
Ex situ conservation 1. "Off-site" conservation; conservation efforts in which the species or population is removed from its natural habitat and managed in a protected environment such as a zoo, botanic garden, or nursery, or stored as dormant seed or gametes for future propagation and use. 2. A captive breeding program that take place in an artificial setting but one within the natural range of the animal. Compare IN SITU CONSERVATION.
Extant Living; having some living representatives at a particular time; i.e., not extinct.
Extent In landscape ecology, the overall size of a study area.
Externality An external cost or benefit imposed on others as the result of some economic activity.
Extinct Not living; describing a species or other group that has no living members.
Extinct in the wild A status for a species that has no living members in its natural setting but has some surviving members in a zoo or other such artificial environment.
Extinction The fact of being extinct, or the process of becoming extinct. Can be *global* (worldwide) or *local* (in a specific area). In the fossil record, it is the last fossil occurrence of individuals of a given species.
Extinction cascade A chain of extinctions triggered by the extinction of a particular species on which many others depend.
Extinction rate The number or proportion of species or other taxa becoming extinct per unit time or after an important geological temporal boundary.
Extinction risk The likelihood that a species or other taxon will disappear or die out within a given area (e.g., in one country or the entire world) and over a definable time period.
Extinction spasmorpulse A catastrophic burst of extinctions, peaking in less than a millennium.
Extinction vortex A complex of interacting mechanisms that lead to the extinction of populations; these mechanisms include loss of genetic diversity as well as environmental and demographic stochasticity.
Extirpation Local extinction; the fact of a group of organisms ceasing to exist in a particular location but still existing elsewhere.
Extremophilic Describing an organism that grows better at, or requires for growth, extreme environmental conditions such as very high (or low) temperature, pressure, and so on.
Extremophile An "extreme lover;" an organism that lives and thrives in a habitat characterized by extremes of temperature, acidity/alkalinity, salinity, light, pressure, or other environmental factors that would prove detrimental or lethal to most other organisms.
Eynbos Evergreen sclerophyll vegetation dominating the Cape Region of South Africa.
Facilitation A process in which one species benefits another, as by mediating stresses.
Facultative Having options; able to function in more than one way; e.g., a parasite that can also live without a host; bacteria that can live in both aerobic and anaerobic environments. Compare OBLIGATE.
Facultative carnivore A carnivorous animal that eats mainly meat but that also consumes non-animal food.
Facultative epiphyte A plant or lichen that commonly grows epiphytically and terrestrially, usually exhibiting preference for one or the other habit in a particular habitat.
Fallow 1. Describing a phase in agriculture when no crop is grown in a cultivated field and volunteer vegetation can grow or regrow; typically done to restore soil fertility or to avoid overproduction. 2. **Lie fallow**. Of a field, to be in this state.

Family In the classification of evolutionary lineages, a category of related organisms that ranks above a genus and below an order. A family usually contains many genera.
Farming intensity or intensification See INTENSIVE AGRICULTURE.
Fat body Storage tissue of arthropods that stores lipids and has endocrine and immunological functions.
Fauna The animal species living in a given area, along with the flora (plant species).
Feedback A change in a system component that triggers effects which will eventually change the original component again. Feedbacks can be positive (*self-reinforcing*) or negative (*self-dampening*).
Feedback loop An ecological response to a human action having environmental consequences, followed by a human behavioral response to ecological changes having economic consequences.
Feed conversion The efficiency of farmed animals to incorporate given feed into biomass; usually expressed as the ratio of weight of feed provided to flesh biomass harvested.
Feedstock The plants or plant-derived products (e.g., pellets) that can be used to produce biofuels. *First-generation* feedstocks are currently under wide cultivation for the production of ethanol and biodiesel, such as corn, soy, sugarcane, and palm oil. *Second-generation* feedstocks (e.g., switchgrass) are currently not widely cultivated for biofuels but have high potential yields.
Fellfield Dry, windswept habitat of cold regions comprising mineral soil, gravels, stones, and rock, dominated by cryptogams (especially mosses and lichens) and, outside the Antarctic continent, by compact cushion-forming phanerogams and short grasses.
Felsic rock Continental crustal rocks relatively rich in silicon and aluminum.
Femtoplankton A classification of plankton according to size; those plankton of the smallest size (0.02–0.2 mm).
Field-deployable Describing a sensor or other such instrument capable of operating outside of a conventional laboratory setting, exposed to the natural elements such as being submerged below the sea surface.
Final host See DEFINITIVE HOST.
Fingerprint A pattern produced by DNA fragments or lipids that represents a community or species.
Fire ecology The study of the occurrence of natural fires in a given ecosystem and the effect of this on the system; e.g., the fact of certain plants germinating via fire-activated seeds.
Fire regime The characteristic pattern of wildfire and bushfire in a given ecosystem, including type, frequency, intensity, severity, season, and extent.
Fire suppression An intentional effort to prevent wildfires in a forest ecosystem; can significantly disturb the natural functioning of the system.
First contact 1. The initial human arrival on a landmass, followed by human colonization. 2. The initial interaction of two previously unconnected cultures; e.g., aboriginals and European settlers.
First-contact extinction A wave of extinction of species native to a continent or island, following the first arrival of humans in that area.
First (fundamental) theorem of welfare economics The mathematical proof that if competitive markets exist for all goods and there are no externalities or other market imperfections, then the market system leads to an outcome of PARETO EFFICIENCY (see).
Fishery 1. A collective effort to gather, collect, or catch wild aquatic wildlife or plants for recreational or commercial purposes, especially fish and shellfish for use as food. 2. A site where such an effort takes place.
Fishing effort The level of fishing activity quantified in terms of the number and power of vessels and duration of fishing.
Fissipedia The suborder of the Carnivora with divided toes, as distinguished from those with finned feet (Pinnipedia).
Fitness The relative contribution of offspring to the next generation. An individual, genotype, or phenotype whose progeny constitutes a large proportion of the succeeding generation has high fitness.
Fixation The process by which certain plants and microorganisms produce organic molecules from inorganic gases. See NITROGEN FIXATION.
Fixation index (F_{ST}) An estimate of the extent of genetic variation among subpopulations. It ranges from 0 to 1, with higher measures indicating more genetic subdivision and lower values indicating less subdivision.
Flagship (species) A charismatic or well-known species that is associated with a given habitat or ecosystem and that may serve as a symbol and rallying point to increase public awareness of the need for conservation action or climate change remediation there; e.g., polar bears in the Arctic.
Flexibility The degree to which alternatives exist for the purpose of reaching a particular conservation goal.
Floodplain Broad, flat areas adjacent to rivers and streams that periodically become inundated during recurring floods. Also spelled **flood plain**.
Flood-recession agriculture A pattern of agriculture in which crops are planted on floodplains as flood waters recede. The growing plants benefit from several factors influenced by the flood, including moist soil, elevated water table, and freshly deposited soil and nutrients.
Flood resistance Submersion ability over a time span of weeks or months.
Flood tolerance Submersion ability over a time span of a few hours up to several days.
Floristic 1. Having to do with flowers or a flora. 2. Describing a plant community that contains a homogeneous suite of species sorted by some classificatory program.
Floristics The study of the type, number, and distribution of plants in a given geographical setting.
Fluctuating resources theory A theory formulated for plants, predicting that pronounced fluctuations in resource availability enhance community invasibility if they coincide with the availability of sufficient propagules to initiate an invasion. In full, **fluctuating resources theory of invasibility**.
Flux the flow of any material measured as quantity per area per unit of time.
Focal landscape An area being evaluated in an HRV (historic range of variability) analysis.
Focal species A species that can be monitored and managed to maintain the integrity of the ecological system of which it is a part.

Foliage projective cover (FPC) The horizontal cover of leaves (in crowns of varying foliage density) in the overstory and understory strata of a plant community.
Food chain A linear representation of the feeding links between consumers and their resources, based on the pattern of a given organism consuming something earlier in the chain and then itself being consumed by something later in the chain. A simple version might show plants (producers) being consumed by plant-eating animals which in turn are consumed by meat-eating animals. A food chain can be a set of species within a food web.
Food pump A sclerotized pump used by hemipterans to suck up the juices (plant or animal) on which they feed.
Food pyramid A graphic representation of the energy relationships of a community, in which the total amount of energy available at each successive trophic level is proportional to the width of the pyramid at the appropriate height.
Food web A set of trophic (feeding) relationships among species in a community; schematically, the pattern often resembles a web of species each connected by trophic interactions with other species.
Footprint The area of land or water covered or affected by a project. This can include direct physical coverage (i.e., the area on which the project actually stands) and the area indirectly affected by the project (through disturbances such as noise emanating from the project). See also CARBON FOOTPRINT; ECOLOGICAL FOOTPRINT.
Foraminifera An order of animal-like protists, many of which secrete calcareous skeletons (tests).
Forb or Phorb A term for nongraminoid herbaceous plants (non-grasses); a shortened form of Euphorbiaceae, the family to which they belong.
Forcing An initial agent of a climate change, such as an increase in solar irradiance (positive forcing) or an accumulation of atmospheric aerosols, as from a volcano (negative forcing).
Forest change process Any activity on forest land that can affect the stand or site and, in particular, the biological diversity. Can include forest degradation or fragmentation, or the establishment of new plantations.
Forest degradation Damage to forest ecosystems through human activities that does not result in the total elimination of forest cover.
Forest enrichment The process of planting trees in degraded or damaged forests to help recover forest density and/or to improve biodiversity by planting species otherwise unable to colonize and regenerate, or that are threatened or vulnerable.
Forest fragmentation See FRAGMENTATION.
Forest land Descriptive term for an area with a minimum tree height of 5 m, a tree canopy cover exceeding 10 percent, and a minimum area of 0.5 ha.
Forest line Another term for the TREE LINE.
Forest management A pattern of human activity intended to derive economic benefit or other utility through multiple and sustainable use of a forest; a complex concept integrating ecological, socioeconomic, and institutional perspectives. Forests can be managed for timber or nontimber forest products, forage for animals, watershed protection, or recreational use.
Forest regeneration The process of forest regrowth on land that was formerly forested; e.g., following a fire.
Forest stand A relatively homogeneous forest landscape unit that can be distinguished from neighboring units by age or composition.
Forest tundra See SUBARCTIC.
Formation A large-scale (subcontinental or continental) vegetation complex defined primarily on the basis of a combination of dominating life forms.
Fossil Anything found in a strata of rocks or sediments that is recognized as the remains of an organism from a former geological time.
Fossil fuels Forms of stored energy produced by the action of pressure and temperature on organic matter buried over geologic time. The major types of fossil fuels are oil, natural gas, and coal.
Fossorial 1. Burrowing; adapted for living or digging underground. 2. A burrowing animal.
Foundation species The group of critical species whose effects and interactions define much of the structure of a community.
Founder effect A random genetic sampling in which only a few organisms derived from a large population initiate a new population. Since these founders carry only a small fraction of the parental population's genetic variability, radically different gene frequencies can become established in the new colony.
Founders 1. See FOUNDER EFFECT (previous). 2. Animals that were collected from their natural range and that have produced progeny in captivity (and are assumed to be unrelated). Thus, these animals are the founding stocks of the captive population. 3. More generally, animals with wild parents that are collected in order to supplement the genetic diversity of an established captive population.
Fragmentation The disruption of an extensive habitat into smaller, isolated patches.
Freon A brand name for CHLOROFLUOROCARBONS.
Front edge A term for the stable margin of a species' range, where population size is growing.
Frugivorous Describing an animal that eats fleshy fruits; e.g., certain birds and primates. Such an animal is a **frugivore**.
Frugivory The fact or process of feeding on fleshy fruits.
Fruiting body The sexual reproductive structure of a fungus.
Frustule The hard, silica-containing skeleton of diatoms (green algae).
Fry Juvenile salmon that have absorbed their yolk sac and emerged from the water bottom.
F_{ST} Fixation index.
Function Any process carried out by an organism or group of organisms. See also ECOSYSTEM FUNCTION.
Functional biodiversity A characterization of a biota that relates to variation in the importance (e.g., relative abundance, biomass, and relative frequency of occurrence) and functional attributes of taxa, and estimated by components such as guild richness, evenness, dominance, and diversity.
Functional connectivity The processes of dispersal and gene flow of organisms among habitat patches.
Functional constraint A limit to the kinds of mutations that can appear in a gene or protein without compromising function. Also called a SELECTIVE CONSTRAINT.

Functional dependency The dependency of one species on another to complete a particular ecosystem process or function; e.g., the dependency of plants on decomposers, or decomposers on plants, to recycle nutrients.
Functional diversity The range and value of those species and organismal traits that influence ecosystem functioning.
Functional extinction Extinction in effect though not necessarily literally in the death of all individuals; can describe a species that is extinct in the wild, that exists but is on the threshold of extinction; that is no longer capable of reproducing, and so on.
Functional gene A recognizable, heritable segment of DNA that encodes for proteins involved with cell metabolism.
Functional groups Polyphyletic suites of species that share ecological characteristics and play equivalent roles in natural communities and ecosystems. Commonly, organisms with convergent anatomical, morphological, physiological, behavioral, biochemical, or trophic characteristics are grouped together. Also called **functional effect groups**.
Functional redundancy An ecosystem property by which more than one species performs a given role so that when one species disappears, the loss of the ecosystem's efficiency as a whole is relatively small. However, if several such species are lost, the system is likely to essentially collapse. Also called **functional similarity**.
Functional trait space A space where species are located according to their functional traits. This may be multidimensional, with each functional trait representing a separate dimension.
Functional traits Those characteristics of species that define their ecological roles.
Functional type A group of species that share morphological and physiological characteristics that result in a common ecological role.
Functional web See INTERACTION WEB.
Fungus A member of the kingdom Fungi, such as mushrooms, molds, or the fungal part of lichens. Members of this kingdom are heterotrophic (i.e., they require a preformed organic source, rather than being able to make their own food), eukaryotic, have rigid cell walls containing chitin, and reproduce by means of spores.
Furca (plural **furcae**) **1**. A forked structure. 2. Specifically, the telson (posterior segment) of crustaceans.
Fynbos A habitat type in southern Africa that is characterized by thickets and low shrubs, in which fire plays a dominant role in ecosystem maintenance. Plant endemism is particularly high in these areas.
GABA receptor One of a class of receptors for GABA (gamma-aminobutyric acid) found in both vertebrates and invertebrates nervous systems, where they mediate rapid, mostly inhibitory synaptic transmission. Insect GABA receptors are the target site for certain insecticides and pesticides.
GABI Great American Biotic Interchange; see GREAT AMERICAN FAUNAL INTERCHANGE.
Gadoid 1. Describing the fish family Gadidae, which includes the true cod and other important food fish. 2. A fish belonging to this family.
GAFI Great American Faunal Interchange.
Gamete A mature sexual reproductive cell, such as a sperm or egg, that can unite with another such cell to form a new organism.
Gametogenesis The developmental process for the formation of functional male and female haploid reproductive cells that combine at fertilization to produce the zygote.
Gametophyte In an organism with an alternation of generations, the haploid, gamete-producing phase.
Gamma (γ) diversity The total number of species within a large area or landscape, encompassing a number of samples from different communities. Compare ALPHA DIVERSITY; BETA DIVERSITY.
Gamma landscape diversity The total number of patch types contained within a geographic region.
Gap 1. An opening in forest vegetation created by disturbances such as clearing, logging, fires, diseases, storms, or the natural death of a tree. The process by which this occurs is **gap dynamics**. 2. A "hole" in the ecological safety net; i.e., a species or class not well represented in areas designed to protect biodiversity. See GAP ANALYSIS (next).
Gap analysis A biodiversity policy tool that compares the actual distribution of a large region's species and vegetation classes to what is found in areas managed for long-term protection of biodiversity. Species and classes that are poorly represented in protected areas are gaps in the protection of biodiversity, and thus are candidates for proactive protection.
Garrigue A name for the low-growing secondary evergreen shrublands that dominate extensive areas of the Mediterranean Basin.
GCM General circulation model.
GBA Global Biodiversity Assessment.
GEF Global Environment Facility.
Gene The functional unit of heredity; the place (locus) on the chromosomes of an organism that encodes for a particular function.
Gene bank A facility where genetic material is stored in the form of seeds, pollen, embryos, or semen, or, in some cases, as live plants or animals living in a field or a greenhouse or other installation.
Gene conversion A process of nonreciprocal (unidirectional) transfer of genetic information.
Gene flow The movement of genes between populations, usually via immigration and mating of whole genotypes, but sometimes single genes may undergo horizontal gene transfer via transfection by microorganisms.
Gene frequency The frequency of an allele within a population.
Gene pool The total genetic diversity found within an individual population or species at a given time.
General circulation model (GCM) A computer model developed to simulate global climate; GCMs are widely used for global climate change predictions.
Generalist A brood parasite species that may parasitize many (up to more than 200) host species.
Genetic Having to do with genes or the study of genes (genetics).
Genetically modified organism (GMO) An organism produced through the introduction of a gene or genes that were transferred from another organism, usually by means of

biotechnology. There is current debate over the role of GMOs in agriculture.

Genetic architecture A characterization of the number and types of genes that underlie a particular trait, and their interactions.

Genetic code The language that specifies how DNA will be translated into amino acid sequences by means of three nucleotide "words" (codons) that specify the 20 amino acids and regulators of transcription (*start* and *stop* codons).

Genetic diversity Genetic variety found within or among species; this allows the population or species to adapt and evolve in response to changing environments and natural selection pressures.

Genetic drift The process of random changes in gene frequency, leading to changes in the genetic composition of a population. The effect of this process is particularly important in small population sizes.

Genetic erosion A loss of genetic diversity in a species, often caused by anthropogenic factors such as land clearing or urbanization.

Genetic load The extent to which an individual is inferior to the best possible individual in the population in terms of fitness, as a consequence of the genes it contains.

Genetic recombination The physical exchange of genetic material between a pair of chromosomes during meiosis.

Genetic variation Differentiation in traits that is attributable to genetic differences among the individuals in a population.

Genetics The scientific study of genes, in the context of an individual cell or organism, the passing of genes from parent to offspring, and the distribution, variation, and alteration of genes in populations.

Genome The complete set of genes of an individual organism.

Genomic Having to do with the genome (see previous).

Genomic cluster See GENOTYPIC CLUSTER.

Genomics The discipline of genetics that focuses on the study of the complete genetic content of species, often by determining the entire DNA sequence of organisms and the expression and function of their genes in relation to various stimuli or metabolic perturbations.

Genotype The genetic makeup of an organism. Compare PHENOTYPE.

Genotypic Relating to the genetic composition of an organism.

Genotypic cluster In a local area, a single group of individuals recognizable on the basis of multiple, unlinked inherited characters or genetic markers.

Gentes (singular **gens)** 1. Brood parasite species with a host-specific lineage. 2. Specifically, lineages of cuckoos in which individual females specialize on a single host and lay mimetic eggs.

Geographic information system (GIS) Any of various computational systems for storing, managing, manipulating, and displaying spatial data. Because landscape models are inherently spatial, strong links to GIS are either built into such models or are required to interface with the model's data.

Geomorphological Having to do with or used in geomorphology (see next).

Geomorphology The study of the surface configuration of the Earth, especially the nature and evolution of current land forms, their relationships to underlying structures, and the history of geological activity as represented by such surface features.

Geophyte A plant with succulent storage tissues such as bulbs, corms, or rhizomes.

Geospatial Having to do with locations on the Earth.

Geothermal Having to do with or produced by the internal heat that exists below the surface of the Earth. Thus, **geothermal energy, geothermal heat(ing)**.

Germplasm 1. Sources of hereditary material. 2. In animal breeding, the breeding animals and fresh or frozen sperm cells, ova, and embryos.

GHG greenhouse gas.

ghost fishing A term for the fact that lost, discarded, or abandoned fishing gear (such as **ghost nets**) can still continue to catch fish.

Gini–Simpson index An index that quantifies the probability that two entities (such as individuals) drawn at random from the data set represent different types (such as species). Often used as a diversity index, but not an expression of diversity itself. [Named for the statisticians C. W. Gini and E. H. Simpson.]

GIS Geographic information system.

Global Biodiversity Assessment (GBA) An independent, peer-reviewed analysis of the biological and social aspects of biodiversity, commissioned by the United Nations Environment Programme.

Global change disturbance An alteration or disturbance significant enough to have global impact on the natural conditions of the atmosphere (such as GHGs produced by human activities), or on various regions throughout the world (such as large-scale deforestation or the widespread introduction of exotic, invasive species).

Global circulation The regular circulation pattern of the Earth's atmosphere, which generates the world's basic climate types; the system involves an Intertropical Convergence zone of low pressure near the equator, subtropical high-pressure belts near the Tropics of Cancer and Capricorn, trade winds flowing from these high-pressure belts toward the equatorial low, and westerly winds in the middle latitudes.

Global climate change See CLIMATE CHANGE.

Global Environment Facility (GEF) An independent financial organization providing grants to developing countries and countries with economies in transition, for projects related to biodiversity, climate change, international waters, land degradation, the ozone layer, and persistent organic pollutants.

Global environmental sustainability See ENVIRONMENTAL SUSTAINABILITY.

Global extinction The fact of a species becoming extinct worldwide, as opposed to *local extinction* which applies to a particular area.

Globalization The process in which businesses and financial markets operate internationally, or increase the extent to which they do so, largely as a result of increased trade, transportation, and communications.

Global warming The warming trend of the Earth's surface temperatures from the late 19th century onward and

particularly in the last several decades, caused by the incremental injection of carbon dioxide and other greenhouse gases (GHGs) into the atmosphere from human activities such as deforestation and fossil fuel consumption. Though literally the term could also apply to earlier natural warming periods in Earth's history, in practice it refers specifically to the current period. See also CLIMATE CHANGE.

Glycogen An insoluble polymer of glucose; the main storage carbohydrate in animals.

GMO genetically modified organism.

Gnetales A small relict order of chiefly tropical or xerophytic gymnosperms that includes the genera Gnetum, Welwitschia, and Ephredra.

Gondwana The southern supercontinent, named after an ancient kingdom in India. Gondwana drifted apart over many millions of years, giving rise to the current Southern Hemisphere land masses of South America, Africa, Australia, and India. Also, **Gondwanaland**.

Gondwanic having to do with or situated in the former supercontinent of Godwana (see previous).

Gonochoristic Describing an individual that is either a male or a female throughout life. This condition is **gonochorism**.

GOS Global Ocean Sampling; a program to study the genetic diversity of microorganisms in the world's oceans.

Grade Another term for a PARAPHYLETIC GROUP.

Gradient A transitional geographic area in which environmental conditions vary.

Gradualism The evolutionary accumulation of small individual quantitative changes in a population, ultimately leading to qualitative change. Contrasted with SALTATION.

Grain A component of spatial scale used in landscape ecology; the size of a single observation.

Graminoids The grasses (family Poaceae) and and also grass-like plants, mostly sedges (family Cyperaceae) and rushes (family Juncaceae).

Granivorous Describing animals that eat seeds or achenes (grass fruits). Such an animal is a **granivore**.

Graze To consume herbaceous plants, including grass, grass-like plants, and forbs.

Grazer A consumer that removes only a part of each prey it attacks and thus rarely kills a prey in the short term. In the traditional sense, this applies to animals that eat plants (herbivores), but it can also apply to nonlethal microbial pathogens and to animals that cause tissue loss, but not death.

Grazing intensity The frequency and closeness of grazing.

Grazing pressure Stress on plant populations due to a high proportion of grazing animals compared to forage available in the given area.

Great American Faunal Interchange The major exchange of fauna (e.g., land mammals, birds) between South and North America after the formation of the Isthmus of Panama, about 2.7 million years ago. Also known as the **Great American Biotic Interchange** or simply **Great Faunal Interchange**.

Great Chain of Being See SCALA NATURAE.

Greenhouse effect The process that traps solar radiation in the lower atmosphere and makes the Earth warmer, in analogy with the way a greenhouse warms incoming air to facilitate the growing of plants.

Greenhouse gas (GHG) A gas in the atmosphere, such as water vapor or carbon dioxide, that can affect climate through the absorption and re-emission of terrestrially emitted infrared radiation. Grennhouse gases are so called because they contribute to the greenhouse effect (see previous).

Grilse An Atlantic salmon that spends only one year at sea before returning to spawn.

Grinnellian niche The sum of the requirements and behaviors expressed by a species in the habitat where it normally occurs. [Described by U.S. naturalist Joseph Grinnell.]

Groundwater A "reservoir" of water occurring below ground in saturated soils and beneath geologic formations.

Group selection Selection between different populations or sub-populations based on attributes of the entire group, where these attributes usually are either selected against or not favored at the level of individual selection.

Growth-form See LIFE-FORM.

Guild A group of species in a community that use similar environmental resources in similar ways.

Ha Hectare.

HAB Harmful algal bloom. See ALGAL BLOOM.

Habitat A living space; the place where an organism or species normally lives, including both its biotic and abiotic elements.

Habitat corridor or connection See CORRIDOR.

Habitat fragmentation The process by which a once continuous area of habitat is divided into two or more disconnected parts, as by roads, farms, fences, logging, and other human activities. It occurs when habitat is lost from the interior, rather than the edge, of a large block of cover.

Habitat island One of the resulting patches that occurs as a result of habitat fragmentation.

Habitat loss A change to an area that prevents a species from living there (e.g. conversion of forest to crop field).

Habitat patch A spatially contiguous area in which environmental variables are similar.

Habitat remnant A small area that is relatively undisturbed and that represents a much larger historical ecosystem.

Habitat restoration Active modification of the current state of a degraded habitat in order to return it to a former, preferred state.

Habitat selection The act or fact of an organism's choosing a combination of available abiotic and biotic elements for the purpose of fulfilling its life history events.

Habitat structure The physical aspects of a habitat; may be characterized by such measures as complexity, heterogeneity, regularity, stratification, and fractal dimensionality.

Hadley cell A pattern of air circulation that causes deserts at about 30° north and 30° south of the equator. The Sun heats the equator, air rises, pressure decreases, moist air moves north and south, cooling as it goes, and then falls onto the spinning earth, drying as it falls. The falling dry air increases pressure preventing the incursion of moist air. [Named for the English meteorologist George Hadley.]

Halophile A salt lover; an organism that is able to tolerate and/or grows optimally at high salt concentrations. Such an organism is **halophilic**.

Haploid 1. Describing a cell with only one complete set of chromosomes, in contrast with a DIPLOID cell with two sets. 2. An organism having such cells.

Haplorrhini One of the two recognized suborders of primates, along with the Strepsirrhini (see); includes New World and Old World monkeys, apes, and tarsiers.
Harmful algal bloom (HAB) See ALGAL BLOOM.
Hatchery A facility in which aquatic species are spawned and resulting juvenile progeny are reared for at least part of their life cycle.
Haustorium (plural **haustoria**) An organ found in parasitic plants that penetrates vascular tissue of the host plant and forms a functional bridge for uptake of water and nutrients from the host.
Heat equator See THERMAL EQUATOR.
Heath Open vegetation dominated by dwarf undershrubs, usually of the family Ericaceae.
Hectare A metric measure of surface equal to 10,000 m^2 or 2.471 acres (U.S.). Abbreviated **ha**.
Helminth One of several classes of parasitic worms, including cestodes (tapeworms), trematodes (flukes), nematodes (roundworms), and monogeneans (flatworms).
Hemelytron The forewing of a heteropteran insect; so called because the anterior part of the wing is opaque and the posterior part is clear (membranous).
Hemiepiphyte A plant that lives part of its life cycle as an epiphyte (i.e., growing nonparasitically on another plant).
Hemimetabolous Having incomplete metamorphosis, that is, showing gradual change from molt to molt, with externally developing wing pads, and lacking any larval and pupal stages.
Hemiparasite A parasite that is also able to carry out photosynthesis; e.g., mistletoe. Also called a SEMIPARASITE; compare HOLOPARASITE.
Herbaceous Having the characteristics of an herb; i.e., having little or no woody tissue and typically persisting for only one growing season in its aboveground growth.
Herbal 1. Having to do with herbs, or medicines derived from herbs. 2. A book or other compilation recording accumulated knowledge of medicinal plants.
Herbicide A chemical used to suppress or kill plants, or to severely interrupt their normal growth processes.
Herbicide resistance The inherited ability of a plant to survive and reproduce following exposure to a dose of herbicide normally lethal to the wild type. Resistance may be naturally occurring, or induced by techniques such as genetic engineering or selection of variants produced by tissue culture or mutagenesis.
Herbicide tolerance The inherent ability of a species to survive and reproduce after herbicide treatment. This indicates that there was no selection or genetic manipulation to make the plant tolerant; i.e., it is naturally tolerant. Thus contrasted with herbicide resistance; see previous.
Herbivorous Describing animals that feed exclusively or mainly on plants. Such animals are **herbivores**.
Herbivory The act or fact of feeding on plants. A distinction can be made between feeding patterns of grazing or browsing, which do not destroy the plant, and one where a single animal eats an entire plant, which is characterized as predation rather than herbivory.
Heritability The proportion of the variance in a trait that is due to additive genetic effects.
Heritable Able to be inherited.
Hermatypic Reef-building; referring to coral species.
Heterochromatin Regions of chromosomes that in general do not include coding DNA, always remaining condensed during a cell's life cycle.
Heterocyst The site for N_2 fixation in some species of filamentous cyanobacteria. A heterocyst is a differentiated cell that may be present terminally or intercalary. It lacks photosystem II, but photosystem I is present, providing a means to generate additional energy (ATP) required to fuel N_2 fixation.
Heterogamete Either of a pair of gametes that differ in form, size, or behavior. The production of such gametes is **heterogamety**.
Heterogeneity 1. A variation in environmental conditions through space (spatial) or time (temporal). 2. The fact of being heterogeneous (see next).
Heterogeneous Made up of differing components; having different parts or elements. Compare HOMOGENEOUS.
Heterokont One of a monophyletic group of eukaryotes, mostly algae, having cells with heterodynamic flagella. Also, STRAMENOPILE.
Heteropteran An insect of the order Heteroptera, the so-called true bugs.
Heterostyly The fact of having two or more kinds of flowers with stamens and pistils of different lengths. Such a plant is **heterostylous**.
Heterotroph Literally, a feeder on others; an organism that is dependent on organic material from an external source to provide carbon for growth; e.g., vertebrates. Such an organism is **heterotrophic**.
Heterotrophic respiration The respiration of those life forms that feed on photosynthetic organisms, including bacteria, fungi, and animals.
Heterotrophy The mode of nutrition in which organisms grow and reproduce on the basis of external sources of organic carbon sources. Compare AUTOTROPHY.
Heterozygosity The presence of alternate alleles at a given locus in a diploid organism (e.g., A_1A_2). Compare HOMOZYGOSITY.
Heterozygous Having two different alleles at a different locus.
Hexapod A member of the Hexapoda, the group including insects and their primitive relatives.
Hibernation A dormant state in certain animals, characterized by inactivity and lower metabolic rates; typically a strategy to conserve energy when food supplies are reduced (as in winter in cold climates).
Hierarchical (habitat) selection The fact that an organism's selection of habitat occurs at varying scales of space and time. First-order habitat selections define species range; second-order define the site of an individual's home range within that species range; third-order specify within home range selections; and fourth-order are fine-scale daily habitat selections.
Hierarchical partitioning The process of partitioning regional diversity between alpha (local) and beta (larger) components.
High seas Those regions of the ocean outside national boundaries, usually beyond 200 miles of any nation's coast.

Hill numbers A continuum of diversity measures that quantify diversity in units of equivalent numbers of equally abundant species. [Developed by British ecologist Mark Hill.]
Hinterland A region lying beyond an urban area, but often influenced by it.
Historic rainforest All land areas with a potential to support the tropical rainforest as determined by the climatic and physiographic conditions, whether they are currently forested or not. This concept provides a baseline to calculate the rainforest loss in a country or region over a historic period.
Historic range of variability (HRV) A description of the full range of landscape characteristics that occurred in the past. Also, **historic range of variation**.
Historical biogeography See BIOGEOGRAPHY.
Historical ecology The study of how human societies and ecosystems change and in turn transform one another through time in local and regional landscapes. Data are drawn from geology, archeology, history, and various other sources.
Historical processes The evolutionary and ecological processes that occur in the recent or distant past including immigration, emigration, speciation, extinction, drift, and/or past selection by the environment.
Holarctic A biotic realm in the temperate, boreal, and arctic regions of the Northern Hemisphere with strong affinities among the regional floras and faunas.
Holistic management A philosophy and practice of livestock grazing management, used by a minority of ranchers in Africa, North America, and Australia, attempting to integrate economic, social, and ecological goals.
Holobiont A collective term for all the organisms engaged in a symbiotic relationship; e.g., the coral animal and the diverse assemblage of microbes that live associated with the coral.
Holocene The epoch in time extending from about 11,700 years ago, approximately when the last ice age ended, to the present day.
Holometabola Insects characterized by complete metamorphosis, a wingless larval stage, and an intermediate pupal stage.
Holomorphology The totality of characters that are indicative of phylogeny (molecular, behavioral, and so on).
Holoparasite A parasitic plant that lacks chlorophyll and cannot photosynthesize. Compare HEMIPARASITE.
Holoplankton See ZOOPLANKTON.
Homeostasis The ability of an organism or other biotic system to maintain a state of relative internal stability in the presence of external change.
Home range The area where an animal typically spends its time; the expanse traversed in meeting life requirements over a given period.
Homogeneous Made up of components that are of the same kind; having uniform parts or elements. Compare HETEROGENEOUS.
Homogenization A blending of species throughout the globe, largely as a result of trade and transportation.
Homoiohydry The ability of an organism to maintain a constant internal water balance independent of fluctuating environmental conditions. Contrasted with POIKILOHYDRY.
Homologous Denoting common ancestry; describing structures, processes, sequences, behaviors, and so on that are derived from a common ancestral structure.
Homology The existence of a similarity that is explained by common ancestry.
Homonymy The fact of the same scientific name being applied to two or more species.
Homoplastic Relating to or exhibiting homoplasy (see next).
Homoplasy A character or character state acquired by parallel or convergent evolution that bears resemblance to a character in a different group.
Homozygosity In a diploid organism, the presence of the same alleles at a given locus (e.g., A_1A_1). Compare HETEROZYGOSITY.
Homozygous Possessing the same gene form (allele) on both chromosomes.
Horizon See SOIL HORIZON.
Horizontal transmission The transmission of pathogens within generations of hosts.
Host The individual that is parasitized by a parasite.
Host range The range of different organisms in which a virus (or a plasmid) is able to replicate successfully.
Hotspot 1. An area with exceptionally high biodiversity, especially one threatened by habitat loss. Called "hot' because such areas are often selected as priority targets for conservation or management efforts. 2. A region that is unusually rich in a particular group of species (e.g., birds), compared with average sites in the same geographic region; contrasted with a COLD SPOT. Also spelled **hot spot**.
HRV historic range of variability.
Human-altered Describing a habitat or ecosystem that has been significantly changed by humans; e.g., the conversion of natural forest into pasture or the reclamation of a wetland for agriculture.
Human-dominated Describing a habitat or ecosystem where human presence and activities strongly influence living and nonliving ecosystem components.
Human ecology A type of ecology focused on the species *Homo sapiens* (humans), including their relationship with their natural, manufactured, social, and cultural, and environments. Can be considered a subset of SOCIAL ECOLOGY.
Humanism A philosophy focusing on the needs, interests, and values of humans. **Ecohumanism** is the belief that this must include concern for the natural environment because of its value to humans.
Human well-being People's condition and capacities allowing secure access to food, water, energy, and shelter of adequate quality to meet their needs, and provide good health as well as social connections.
Husbandry The practice of raising livestock and growing crops.
Hutchinsonian niche The set of environmental conditions, or opportunities, that will permit a species to exist indefinitely. [Named for the British-American ecologist G. Evelyn Hutchinson.]
Hutchinsonian ratio The body size ratio of larger species over smaller species in a pair of species; according to this coexisting species are expected to have a greater body size ratio than would occur by chance, because competition prevents coexistence of species that are morphologically too similar.
Hybrid An individual that results from crossing between individuals from two or more populations, races, subspecies,

species, and so on, including individuals that are F1s, F2s, and the set of all backcrosses.

Hybrid inviability A phenomenon whereby one or both sexes of progeny produced in crosses between two different species is unable to survive.

Hybridization Mating between individuals of two different populations, usually classified as separate species; mixing of their genomes is not required.

Hybrid sterility A phenomenon in which one or both sexes of progeny produced in crosses between two different species are able to survive, yet are unable to reproduce.

Hybrid swarm A mixture of hybrid genotypes, including F1s, F2s, and backcrosses, due to hybridization between two or more species that co-occur in a locality.

Hybrid zone An area of overlap or point of contact between two populations that are distinguishable based on one or more heritable characters where viable or partially fertile hybrids are formed.

Hydrologic(al) Having to do with water or the study of water.

Hydrologic connectivity The ability for water to move between portions of a river system, such as between a river channel and floodplain surfaces.

Hydrologic regime The aggregate set of variables describing the behavior of water in wetlands, including water depth, magnitude and frequency of water level fluctuations, seasonal pattern of water fluctuations, direction and velocity of waterflows, and water residence time.

Hydrology The scientific study of the properties, distribution, movement, and effects of water on the Earth's surface.

Hydrophilous 1. Water-loving; growing or thriving in water. 2. Pollinated by or in water.

Hydrophily Underwater pollination developed by most seagrasses and many freshwater angiosperms.

Hydrophyte A plant capable of growing and persisting in saturated or flooded soils. Such a plant is **hydrophytic**.

Hydrothermal plume A plume created by the heat of volcanic processes in the ocean, rising as "black smoker" effluents that mix turbulently with the surrounding seawater, then become dilute and eventually reach neutral buoyancy (typically at about 200 m above the black smoker source. Once neutral, these plumes spread laterally and are detectable by chemical and physical tracers.

Hypercycle A cyclic sequence of self-supporting reactions between primitive prebiotic biomolecules, nucleic acids, and proteins. The **hypercyclic** organization of reacting systems is postulated to explain the spontaneous emergence of replicating systems. As a result of the **hypercyclic reaction principle**, functional characteristics of replicating molecules (i.e., phenotypes) are connected to their hereditary characteristics or their genotypes.

Hyperparasite A parasite living on or in another parasite. Such an organism is **hyperparasitic**.

Hyperparasitism The fact of living parasitically on or in another parasite.

Hyperparasitoid A parasitoid of a parasitoid; e.g., a parasitoid wasp larva living in a parasitoid fly larva that feeds on a beetle.

Hypersaline More salty than sea water.

Hyperthermophile An extreme heat-lover; an organism that grow optimally at temperatures higher than 80° C. Such an organism is **hyperthermophilic**.

Hyperthermophily The fact of growing optimally at temperatures higher than 80^0 C.

Hyphae (singular **hypha**) The feeding (vegetative) threads of most fungi. The hyphae of one organism are sometimes referred to as *mycelia*.

Hypodermis The cellular, subcuticular layer that secretes the cuticle of annelids, nematodes, arthropods, and various other invertebrates.

Hypognathous Describing the position of the head when the mouth is directed toward the ventral side of the body.

Hyporheic zone The area of saturated soils beneath a stream or a river channel; it interacts with the stream through the processes of hydraulic upwelling and downwelling.

Hypotelminorheic A persistent wet spot, a kind of perched aquifer, rich in organic matter, underlain by a clay layer typically 5–50 cm beneath the surface, with a drainage area typically less than 10,000 m^2.

Hypoxia 1. A lack of oxygen; a decreased oxygen supply. 2. Specifically, a condition in which water has depressed dissolved oxygen levels that generally are too low to sustain healthy populations of most fish species for extended periods.

Hypoxic 1. Lacking oxygen; characterized by decreased levels of oxygen. 2. Specifically, describing water with depressed oxygen levels; many fish will actively avoid hypoxic areas.

Hypsodont A high-crowned cheek tooth commonly found in grazing mammals.

Hysteretic response A phenomenon in which the response of a physical system to an external influence depends not only on the present magnitude of that influence, but also on the previous history of the system.

Idiobiont A parasitoid that develops on a paralyzed, incapacitated host.

Igapó 1. Vegetation periodically flooded by acidic black-water or clear-water rivers, as in the Amazon basin. 2. A floodplain with such vegetation.

ILUC Indirect land-use change.

Imago An adult insect; the final developmental stage when insects possess wings.

Immobilization The result of microbial decomposition of organic matter in which nutrient elements (particularly nitrogen) are taken up into the microbial biomass, rendering them unavailable for plant uptake. See also MINERALIZATION.

Impoverishment On an island, a paucity of species relative to the adjacent mainland.

Inbreeding Mating between close relatives; this results in progeny that carry two copies of the same allele at many loci throughout the genome.

Inbreeding depression Reduction in fitness due to inbreeding.

Incidence The number of samples containing at least one of a given species in a census.

Inclusive fitness An individual's lifetime reproductive output if not assisted by others, plus the added reproduction it confers on each relative it helps, times the proportion r of genes identical by recent descent it shares with that relative. It thus represents the common interest of the autosomal genome, which is what natural selection maximizes.

Inclusive wealth The sum total of capital assets or human and Earth system properties that can be used to provide the flow of goods and services that contribute to well-being.
Index of aridity The ratio of mean annual precipitation to mean annual potential evapotranspiration.
Indicator A species or community that enables observers to evaluate environmental conditions and detect changes.
Indicator species are normally surrogates of other species in the area of interest and are usually sensitive to environmental change. Environmental variables may also be used as indicators.
Indigenous 1. Originating in and living naturally in a certain place; native. 2. Relating to indigenous peoples (see below).
Indigenous knowledge Traditional understandings of indigenous peoples, often orally transmitted from generation to generation.
Indigenous peoples Groups of human beings who have resided in the same geographical area for many generations, usually many centuries, and who possess legends, proverbs, genealogies, languages, and other unique cultural features linking them to this site.
Indirect effect An effect on a third species or trophic group owing to a direct interaction between two species or trophic groups. Trophic cascades are the result of the indirect effect of predator–prey interactions on a third group.
Indirect land-use change (ILUC) Conversion of land from one land-use category to another, induced by the expansion of biofuel production elsewhere.
Indirect use values Benefits gained from environmental goods and services that are derived from supporting and protecting activities as opposed to direct use of the resource, such as coastal habitats serving as breeding and nursery grounds for off-shore fisheries, coral reefs providing protection against storm surge, or upper watershed forests controlling soil erosion and runoff. Compare DIRECT USE VALUES.
Individual-based (abundance) data A common form of data in biodiversity surveys. The data set consists of a vector of the abundances of different species; used when an investigator randomly samples individual organisms.
Individualism (of species) The observation that distributions and abilities of most species do not exactly coincide because each species is the product of a unique evolutionary history. Coevolution and convergence may occur, but rarely are these processes so complete that groups of species are distributed as a unit or superorganism.
Individual selection Selection driven by differences in the net reproduction of individual organisms.
Individual transferable quota (ITQ) A type of market-based incentive in which regulators set an aggregate limit on harvests of an open access resource (typically fish), assign rights to the allowable harvest to individual participants, and permit participants to trade those rights.
Induced defense A plant defense, including both chemical and physical defenses, that is produced, at least in final form, only after the plant has been damaged by herbivores or pathogens.
Industrial agriculture A modern form of agriculture that differs from TRADITIONAL AGRICULTURE (see) in the use of elaborate and expensive machinery, the control of pests with toxic chemicals rather than through biological controls, fertilization by synthetic rather than organic products, excessive consumption of water, and farm ownership and management by corporations rather than individuals. Industrial agriculture has significantly greater environmental impact than traditional agriculture. Also known as **industrialized agriculture**.
Infauna Animals living within sediments.
Infection The presence of pathogens within a host's body.
Infectious disease A state of compromised health in a host caused by a pathogen infection.
Input environment A collective term for all energy and materials moving into a given system.
Insecticide A toxic chemical used to suppress or kill insects, or to severely interrupt their normal growth processes.
Insecticide resistance The inherited ability of an insect to survive and reproduce following exposure to a dose of insecticide normally expected to be lethal to individuals of this species.
Inselberg An isolated hill, rock, dome, small mountain, or the like that stands out from the surrounding lower elevations. [German for "Island Mountain."]
In situ Literally, "in position;" in its natural setting, as opposed to a laboratory, zoo, or other artificial setting (*ex situ*).
In situ conservation 1. Conservation of natural ecosystems and habitats, and the maintenance and recovery of viable populations of species, in their natural surroundings. 2. Conservation of domesticated or cultivated species in the surroundings where they have developed their distinctive properties. Compare EX SITU CONSERVATION.
Instar A stage between molts of immature insects.
Instrumental value The value of something in terms of human interests or desires.
Insurance hypothesis The principle that biodiversity "insures" ecosystem function, because more species guarantee that some will continue to function even if others fail, thereby enhancing the capacity to recover from and mitigate the risks caused by disturbance. According to this, biodiversity can be said to have **insurance value**, because it reduces risk for those who make use of a given ecosystem service.
Integrated conservation and development A project that links biodiversity conservation, usually of a protected area, with local socioeconomic development activities in which alternative incomes or livelihoods are introduced to reduce pressure on local natural resources.
Integrated weed management An approach for suppressing weeds that combines information on the biology and ecology of the weed with all available control technologies, so that no one method is used exclusively.
Intensification See INTENSIVE AGRICULTURE.
Intensity 1. The number of parasites per infected host. 2. See INTENSIVE AGRICULTURE.
Intensive agriculture The management of agricultural land to increase production, mainly through high-yielding crop varieties, chemical fertilizers and pesticides, increased tillage and irrigation, shorter rotations, larger fields, and greater mechanization. May also include converting natural habitat to cropland, fragmenting natural habitat, avoiding fallows, and removal of hedgerows. See also INDUSTRIAL AGRICULTURE.

Interaction web A subset of species that through their interactions and their responses to abiotic factors make up the dynamic core of food webs or communities. These webs include keystone species, dominants, and other strong interactors. Also known as a **functional web**.

Intercropping The agricultural system of growing two or more crops simultaneously on the same field. According to row arrangement and relative growth time, intercropping can be divided in to three types. In **mixed intercropping** the crops are grown with no distinct row arrangement. In **relay intercropping** the crops are grown during part of the life cycle of each. (A second crop is planted after the first crop has reached its reproductive stage of growth but before it is ready for harvest.) In **strip intercropping** the crops are grown in different strips that are wide enough to permit independent cultivation but narrow enough for the crops to interact agronomically.

Interference competition Interaction among two or more species that use a common resource that is not limiting, in which one species is harmed by having its access to the resource restricted.

Intergenerational equity Equality and fairness in the well-being of people in future different generations relative to current generations.

Intermediate disturbance (hypothesis) The proposal that some level of disturbance is necessary to maintain biodiversity.

Intermediate host A host that harbors sexually immature, developing stages of a parasite. Also known as a SECONDARY HOST.

International Species Information System (ISIS) A central repository for zoo animal records, founded in 1973; it has also developed the computer programs that most zoos use for keeping their animal records.

Interspecific Between species; involving organisms of different species. Contrasted with INTRASPECIFIC.

Interspecific brood parasite A brood parasites that lays its eggs in the nests of other species.

Interstices The spaces between sediment particles, such as sand or silt grains.

Interstitial Having to do with or living in interstices (see previous).

Intertropical convergence zone (ITCZ) A low-latitude region characterized by warm air masses and convectional rainfall.

Intraguild predation Species interaction in which predators feed on herbivores as well as other predators, and trophic levels are not well defined.

Intraspecific Within species; involving organisms of the same species. Contrasted with INTERSPECIFIC.

Intraspecific parasitism A parasitic association of members of the same species.

Intrinsic rate of growth A parameter, often designated as the variable *r*, reflecting the rate of change in population size due to births and deaths when resources are not limiting.

Intrinsic value The value of something independent of its value to people.

Introduced species Species transported by humans to regions outside their natural geographic range.

Introduction The placement of individual organisms by people into a habitat for purposes of establishing a population in a place where it does not currently occur.

Introgression The permanent transfer of genes from one or more species, subspecies, or race into another by means of hybridization and backcrossing.

Introns Generally noncoding segments of genes, situated between exons and removed before translation of messenger RNA to proteins.

Invasibility The properties of a community, habitat, or ecosystem that determine its inherent vulnerability to invasion.

Invasion The process in which an organism enters an ecosystem from some other geographic region, often as the direct or indirect result of human activity, and disrupts the ecosystem's composition, structure, or function.

Invasional meltdown The compounded effect on an ecological community of successful and successive invasions of alien species benefiting from the previous introduction of the other.

Invasive Describing an organism that has entered (invaded) an ecosystem from elsewhere, and that has the potential to spread over the area and displace indigenous species, causing environmental and/or economic harm. Thus, **invasive species, invasive plant**, and so on.

Invasiveness The fact of being invasive; the features of an alien organism, such as their life-history traits and modes of reproduction, that define their capacity to invade.

Invasive weeds Introduced plant species that establish self-maintaining populations and spread into new areas where they frustrate human intentions in production and natural landscapes.

Invertebrate An animal without a backbone (vertebrae); i.e., most of the animal kingdom, ranging from unicellular protozoa to multicellular, complex organisms such as insects.

Invisible hand The term used by the Scottish economist Adam Smith to describe the capacity of a decentralized market system to attain efficiency through self-governing mechanisms.

IPAT A mathematical formula for calculating human impact on the environment; expressed as Impact = Population x Affluence x Technology.

Irreplaceability The degree to which a region is necessary as part of a comprehensive conservation strategy. A region with high levels of endemism has high irreplaceability, because it cannot be replaced by others if the endemic species are to be conserved.

Irreplaceable Having the property of irreplaceability (see previous).

ISIS International Species Information System.

Island biogeography theory The theory that the number of species in the biota of an island (or island-like habitat) is in dynamic equilibrium, with species frequently going extinct on the island and new species frequently arriving.

Isocline A line along which some property remains constant.

Isolating mechanism Any intrinsic or extrinsic mechanism or barrier that inhibits the free exchange of genes between populations.

Iteroparity The fact of being capable of repeat breeding, or the process of doing this. Compare SEMELPARITY.
Iteroparous Capable of breeding more than once.
ITCZ Intertropical convergence zone.
ITQ Individual transferable quota.
IUCN International Union for Conservation of Nature; a global environmental organization dedicated to conserving biodiversity, founded in 1948 and based in Switzerland. Noted especially for the IUCN Red List (see next).
IUCN Red List A widely cited, comprehensive compilation of the extinction risk of species on a local or global basis. In full, IUCN Red List of Threatened Species.
Jack Term for a sexually precocious male salmon that spends one winter or less at sea before returning to its natal stream to spawn.
Joint determination The fact that ecological and economic systems mutually affect each other.
Jumping gene Another term for a TRANSPOSON.
Kaldor–Hicks efficiency An economic condition in which those participants who are made worse off by a change to the system could in theory be compensated by those who are made better off, and would be willing to accept this compensation. An alternative to the economic equilibrium described by PARETO EFFICIENCY. [Named for the British economists Nicholas Kaldor and John Hicks.] Also known as **potential Pareto efficiency**.
Karst A landscape in which the primary geomorphic agent is solution rather than erosion; typically formed in carbonates, landforms including caves, sinkholes, blind valleys, and large springs.
Kelt A spawned-out Atlantic salmon or steelhead that is returning to the ocean to recuperate and spawn again.
Key innovation A property of a species that promotes the process of speciation.
Key-industry species Prey of intermediate trophic status that support a large group of consumers.
Keystone species A species whose effects on the structure, dynamics, and functioning of the community is disproportionately large relative to its abundance. Also, **keystone**.
Kinetic energy See ENERGY.
Kleptoplastic Having the ability to harvest chloroplasts from algae; these are then used by the secondary host to make photosynthetic products. This phenomenon is **kletoplasty**.
Koinobiont A parasitoid that develops on a mobile, active host.
Korarchaeota A proposed third kingdom within the domain Archaea, including a small group of ribosomal RNA sequences retrieved from geothermally heated sediments. [From Greek *koros*, young man and *archaios*, ancient; for the early divergence of this group during the ancient evolution of the Archaea.]
Kranz anatomy Specialized anatomy of the C_4 plant leaf in which the bundle sheath (BS) tissue is enlarged and enriched with chloroplasts, whereas the mesophyll is reduced in size and often forms a lighter green halo around the BS. This produces a wreath-like ('Kranz' in the original German) appearance.
K-T An abbreviation for Cretaceous-Tertiary, usually in reference to the K-T event or boundary (see next).
K-T event A notable large-scale extinction event occurring about 65 million years ago, at the boundary of the Cretaceous and the Tertiary (**K-T boundary**), involving the extinction of about 70 percent of extant species, including the dinosaurs and many other land-dwelling vertebrates.
Kuznets curve A hypothesized trend in which pollution and other environmental degradation initially rise, then level off, and eventually decrease as incomes increase and the national economy develops. [Proposed by the Russian-American economist Simon Kuznets.]
Kwongan Evergreen heathlands that cover extensive areas of southwestern Australia.
Land cover The physical materials covering the surface of the earth, natural or man-made; e.g., water, forests, grassland, bare ground, buildings, roads, and so on.
Land degradation Reduction or loss of the biological and economic productivity and complexity of terrestrial ecosystems; see DEGRADATION.
Land equivalent ratio (LER) The area needed for sole cropping to produce the same amount of crops as would be produced in one hectare of intercropping or mixed cropping.
Land ethic A philosophy of proper treatment of lands and the natural communities on them, as opposed to valuing land merely as property.
Landrace A traditional local variety of a domesticated animal or plant species that has developed largely by natural processes, through adaptation to the physical and cultural environment in a given geographic region. The term TRADITIONAL VARIETY is sometimes applied to plant landraces. [From the sense that it is a race (breed) peculiar to the land where it lives.]
Landscape 1. The visible features of an area of the natural terrestrial world, including physical aspects such as mountains or rivers, and also native vegetation. 2. A specific area having consistent features of this type; e.g., a desert or forest landscape.
Landscape complementation The degree to which a landscape provides all necessary cover types for a species that requires multiple cover types to complete its life cycle.
Landscape connectivity See CONNECTIVITY.
Landscape fragmentation See FRAGMENTATION.
Landscape heterogeneity The variability in land cover types within a given landscape.
Landscape legacy The long-term impact of historical events on ecosystem structure, composition, or function.
Landscape matrix See MATRIX.
Landscape patch See PATCH.
Land sparing The spatial separation of biodiversity conservation from agriculture.
Land use The set of human activities within a landscape and their impacts on natural processes, such as physical, chemical, and biological cycles. Land use is often classified in major categories such as cropland, pasture, plantation forest, and natural forest.
Land-use change The changes in the way land is used at a given location, for example, when a forested land is converted to agricultural fields or when a forestry plantation is changed to other types of use.
La Niña Southern Oscillation See EL NIÑO SOUTHERN OSCILLATION.

Larvae (singular **larva**) Early stages in the development of an organism; for invertebrates, often morphologically quite distinct from the adult.
Larval Having to do with or being larvae.
Larval parasite An organism that is parasitic only at a larval stage.
Late Quaternary The most recent period of the geologic time scale.
Late Quaternary extinction (event) Selective prehistoric extinctions, typically catastrophic, eliminating within the past 40,000 years two-thirds or more of the large land mammals of America, Australia, and Madagascar and at least half the species of land birds on remote islands of the Pacific. Humans were present or suspected to be present in virtually all cases of such extinctions.
Latent parasitism Parasitism occurring without obvious symptoms.
Latitudinal biodiversity gradient The well-documented trend for a greater number of species in tropical ecosystems than in temperate or polar ecosystems.
LCA Life cycle assessment.
Leading edge The dynamic margin of a species' range, where it is expanding into neighboring unoccupied areas.
Leaf area index The single-sided total leaf area of vegetation per unit area of land.
Leaf beetle One of the Chrysomelidae, a large, widely distributed family of beetles that includes several significant agricultural pests.
Leakage A term for the displacement of environmentally harmful activities outside the spatial or temporal boundaries of a policy or project.
Least concern A classification for organisms not qualifying or close to qualifying for any extinction threat category.
Legacy ecosystem An ecosystems that carries an intact "memory" of a change in some physical, chemical, or structural attribute or a change in species composition that modifies the resistance and resilience characteristics of the ecosystem.
LER land equivalent ratio.
Lethal equivalent A group of mutant alleles that would cause an average of one death if homozygous; for example, one lethal equivalent might represent two mutant alleles, each with a 50 percent probability of causing death, or any other combination of mutant alleles that would produce an average of one death.
Levee 1. A structure built along rivers that is intended to contain floodwaters and prevent flooding of land behind the structure. Also referred to as a **dike**. 2. A similar natural feature having the same effect, formed through geomorphic processes.
Liana Any of various woody climbing plants with relatively long, thick stems that use trees as support to gain access to the canopy; they generally grow in mature habitats.
Lichen A composite organism consisting of a fungus (the *mycobiont*) and an alga or a cyanobacteria (the *phycobiont*) living in a symbiotic relationship.
Life cycle assessment (LCA) An analytic framework to assess the full environmental impacts of a given product or service, from raw material extraction, through production, use, and disposal. Also known as **life cycle analysis**.
Life-form The size and stature of a plant under natural life conditions. Environmental constraints can cause the life-form to differ substantially from that of a plant that develops under more favorable conditions, where genotype morphology, as the **growth-form**, finds full expression. For instance, the growth form *tree* may be modified to the life-form *shrub* in the alpine zone.
Light use efficiency (LUE) For crops, the slope of the linear relationship between accumulated biomass and cumulative intercepted light.
Limiting nutrient See NUTRIENT-LIMITED.
Limiting resource 1. The resource that most limits primary production in ecosystems (often nitrogen). 2. Any ecosystem resource that is the one most able to restrict the ability of a certain organism or species to grow, survive, and reproduce in that area; it may be abiotic (e.g., temperature) or biotic (e.g., predators). Also, **limiting factor**.
Limnology The study of the ecological and physical characteristics of lakes and other inland bodies of water. One who conducts such studies is a **limnologist**.
Linnean system or hierarchy The hierarchical arrangement of inclusive categorical ranks in which, apart from the lowest rank, subordinates the members of all lower ranks; it contrasts with exclusive classifications (such as SCALA NATURAE). [From the original version of such systems devised by the Swedish botanist Carl Linnaeus.]
Litter Dead organic matter, such as leaves and branches, that is deposited as the top soil layer.
Littoral 1. having to do with or situated near the shore of a body of water. 2. having to do with or living in the littoral zone (see next).
Littoral zone The shoreline zone of a lake or river, between land and open water, where sunlight penetrates to a wetland's substrate and supports rooted plant growth.
Livelihood investment A non-monetary payment to compensate for opportunity costs of a change in land use; can include alternative livelihoods, alternative food sources, and education investments, among others.
Living dead An individual devoid of the ecological circumstances that allow it to be a reproductive member of its population, but able to live out its own physiological life. Living dead species are most easily observed as large trees remaining on the agroscape, but they are also present in natural ecosystems.
Llanos A region of tropical South America, on the east side of the Andean range of Colombia and Venezuela. Llanos landscapes occupy lower elevations and the landforms vary from flat to rolling terrain. The dominant vegetation is savannah with areas of dry forest, gallery forest, and morichales.
Local adaptation The process by which populations of organisms become adapted to their local environment or ecological niche. Populations that are **locally adapted** generally exhibit the highest fitness in their native environment and reduced fitness in other, contrasting locations or conditions.
Local community A set of individual organisms in a region of space that is typically small, in which local speciation is assumed to have a negligible impact on community dynamics,

and which may be a part of or connected to a much larger metacommunity.

Local extinction The fact of a species ceasing to exist in an area that it had historically occupied.

Local species richness The number of species found at a local site; distinguished from regional or global species richness that aggregates the number of species across a number of individual sites.

Locus (plural **loci**) The physical location of a gene on a chromosome.

Logging The operation of harvesting trees, sawing them into appropriate lengths, and transporting them to a sawmill.

Logistic growth Regulated population growth that follows the logistic equation $dN/dt = rN(1 - N/K)$. Populations growing according to this equation increase rapidly at low densities and the growth rate decreases as they approach carrying capacity (K).

Lognormal distribution A statistical distribution that is normal or Gaussian (a bell curve) when the logarithm of the original data is used. Species abundance data from many communities fit this distribution well.

Lotka–Volterra competition model A model describing the per-capita growth rates of two competing species as linear, declining functions of the abundances of each species. [Developed independently by the mathematicians Albert J. Lotka and Vito Volterra.]

LSU rDNA The gene in DNA that codes for the ribosomal RNA in the large subunit (LSU) of the ribosome. This is 23 S rRNA in prokaryotes and 28 S rRNA in eukaryotes.

LUE light use efficiency.

Lysogenic A bacterium that has a temperate virus integrated into its genome. So called because it may **lyse** (be destroyed or decomposed) at some later time as a result of the virus excising from the genome and initiating replication (induction). This occurs spontaneously with low probability, or with high probability in response to a stress to the host cell.

Lytic virus A virus that does not integrate into the host genome, but initiates replication and ultimately lyses the cell.

Ma An abbreviation of the Latin "mega-annum;" used by paleontologists to indicate dates millions of years before the present time.

Macroalgae See ALGAE.

Macrobiota Those organisms large enough to be seen with the naked eye, usually greater than 1 mm.

Macroclimate A generalized climate; see MICROCLIMATE.

Macrocosm A context or system that reflects one of its components on a large scale.

Macroevolution Evolution leading to the existence of new species.

Macrofauna Invertebrate organisms living in or on sediments and large enough to be retained on a 300- or 500-μm sieve.

Macroinvertebrate An organism lacking a backbone (vertebrae) and generally visible to the unaided human eye.

Macroparasite A parasite large enough to be seen with the naked eye, such as a leech or worm.

Macroplankton A classification of plankton according to size; those plankton of relatively large size (2–20 cm).

Macropod A marsupial in the family Macropodidae, the kangaroos and wallabies.

Macropterous Having long or large wings or fins.

Macroscopic Large enough to be visible to the unaided human eye.

Macrotidal Describing a spring tide range of more than 4 m.

Mafia effect or behavior A term for the fact that hosts have been observed to tolerate the presence of the eggs or nestlings of brood parasites rather than ejecting them, because the parasite can retaliate by destroying the nest entirely. [Likened to the way citizens will endure the existence of the Mafia in their community, because any opposition would result in extreme retaliation.]

Mafic Describing rocks relatively rich in magnesium and iron.

Major ecosystem type Groups of ecoregions that share minimum area requirements for conservation, response characteristics to major disturbance, and similar levels of biodiversity (i.e., the rate of species turnover with distance).

Malacology The scientific study of mollusks. One who conducts such studies is a **malacologist**.

Malesia The Malay Peninsula, Malay archipelago, and New Guinea. Biogeographically, this combines Sundaland, Wallacea (including the Philippines), and New Guinea.

Mammal A member of the order Mammalia, including species that provide milk for their young and have fur or hair. They typically (but not exclusively) bear live young.

Managed relocation Intentional movement by humans of organisms from a place where they currently live to a new region where they are likely to persist in the future, especially as a strategy to deal with human-caused climate change.

Management The efforts of humans to select, plan, organize, and implement programs designed to achieve specified goals. In the context of the natural environment, such activities can range from protective measures to ensure that human influences on natural resources are minimized to greater interventions required to maintain diversity, install facilities, control populations, and eliminate unwanted elements.

Mangal A mangrove tree habitat, or the trees themselves.

Mangrove 1. Any of various trees and large shrubs, especially of the genus Rhizophora, that have intertwining aerial roots and grow densely in salty coastal swamps of tropical and subtropical regions. 2. An ecosystem dominated by mangroves and associated vegetation; a unique type of system that is often the focus of conservation or restoration efforts.

Mantel test A statistical test of the correlation between two matrices that is often used in ecology; e.g., a geographic and genetic distance matrix in landscape genetics. [Named for U.S. statistician Nathan Mantel.]

Mantle In mollusks, an ectodermal tissue layer that secretes calcium carbonate in the form of spicules or shell.

Maquis Vegetation cover of the Mediterranean Basin dominated by evergreen sclerophyllous (leathery-leaved) shrubs and trees.

Marginal value The economic value (**marginal benefit** or **cost**) of the next incremental unit of something. In an ecological context, marginal values are those associated with managing the next small unit of an ecosystem in a particular way (as by preserving, rather than clearing, the next unit of forest). They can also be the partial contribution of natural capital to a final good that is produced with other inputs; e.g., the marginal value of irrigation water for crop production is

the value of the incremental crop yield that can be attributed to irrigation, rather than to labor, fertilizer inputs, and the like.
Marimba Elevated flooring made of wood, used in flooded areas for placing cattle or plants during river flood periods.
Mariculture The commercial farming of aquatic organisms specifically in marine (saltwater) environments.
Marine Having to do with or situated in the ocean, including coastal, intertidal, and near shore settings as well as the open ocean.
Marine protected area (MPA) A clearly defined marine space recognized, dedicated, and managed to achieve the long-term conservation of nature with associated ecosystem services and cultural values.
Marine reserve A subset of a marine protected area (see previous); an area of ocean completely protected from all destructive and extractive activities, such as fishing, mining, or other consumptive use.
Market-based Describing a policy, program, incentive, and so on that is implemented by the encouragement of certain financial incentives rather than by government mandates.
Market-based command and control A policy instrument in which regulated firms must meet individual environmental targets, often requiring the use of specific technologies. Such policies contrast with market-based incentives (see next), which allow firms more flexibility in how to meet aggregate environmental targets.
Market-based incentive A policy designed to change behavior by altering the price paid, or cost borne, by a person, business, or other entity engaged in an activity that affects biodiversity.
Market-based instrument A policy mechanism in which a change in technology, behavior, or the mix of inputs and outputs is encouraged through financial incentives, such as subsidies, taxes, or market creation.
Market economy An organization of economic activity in which private individuals buy and sell goods at prices that (ideally) balance supply and demand.
Market failure In a market economy, a situation in which the allocation of goods and services to consumers does not take place in an efficient way. This can occur when the free market confers benefits on certain participants for acting in a way that is not beneficial to the system as a whole.
Market-mediated effect Changes in the supply and demand of other products due to the production of a given product.
Market value chain The sequence of activities involved in producing raw materials and transforming them into products that can be purchased by final consumers. It can be used as a strategy to create incentives for farmers to conserve landraces with traits that are valued by consumers.
Marsh A wetland dominated by herbaceous species of plants (e.g., cattails, sedges, grasses, floating ferns) and typically occurring on mineral soils. Floating-leaved and submerged species of plants dominate the parts of marshes that grade in to open water.
Marsupial One of the mammals (e.g., kangaroos) without a placenta and with a pouch to carry the young.
Marsupium The folds of skin that envelope the mammary glands and provide protection to infants: found in both metatherian (marsupial) and protherian (monotreme) mammals.
Mass extinction One of the rare events when extinction rates escalate and extinction reaches devastating magnitudes in a relatively short period of geological time. Mass extinction events affect species from a wide variety of taxa and have a global impact. There have been five mass extinction events in Earth's history with magnitudes of 75 percent or more of species loss.
Mass ratio hypothesis A hypothesis stating that ecosystem processes are largely determined by the dominant contributors of the overall plant biomass; i.e., dominant species will exert greater influence on processes than will subordinate species.
Mast fruiting (seeding) The production of many fruits (seeds) by a plant every two or more years, in regional synchrony with other plants of the same species. *Community-wide* mast fruiting occurs with other plants of different species.
Matorral Evergreen sclerophyllous (leathery-leaved) shrublands that dominate large areas of central Chile.
Matrix The most extensive and interconnected mosaic of habitats in a particular landscape; the dominant component of the landscape that exerts a major influence on ecosystem processes.
Maximum sustainable yield The maximum average level of natural resources that can be harvested over time without reducing future potential; e.g., the maximum fish catch that can be removed from a population over a long time period.
MDNA Mitochondrial DNA.
Mechanistic model A model of population dynamics that is explicit about resource consumption, the relationship of consumption with demography, and mortality factors.
Median or medial Along or toward the midline of the body.
Mediterranean-type ecosystem (MTE) A habitat characterized by mild wet winters and warm dry summers. MTEs occur in the Mediterranean region itself, California, central Chile, the Cape Region of South Africa, and southwestern and South Australia, all at northern or southern latitudes of 30–35°.
Megacity A modern city with a large, expanding population, characterized by high consumption levels of energy, water, and food from sources outside the city.
Megadiversity The fact of an area or a country possessing a much larger proportion of species than would be expected by its extent, latitudinal position, and other factors. Such a region is **megadiverse**.
Megafauna Large terrestrial animals that are wolf-sized, deer-sized, and larger. Common standards for inclusion are a body weight of 44 kg (100 lbs) or 100 kg (220 lbs). The term is often used in reference to the many species of large New World mammals that became extinct during the Pleistocene epoch.
Megaplankton A classification of plankton according to size; those plankton of the largest size (2–20 cm).
Meiofauna Animals small enough to pass through a 500-μm sieve but large enough to be retained on a 44- or 63-μm sieve.
Meroplankton See ZOOPLANKTON.
Mesectoderm See NEURAL CREST.
Mesh size The size of the holes in a fishing net.
Mesic Describing a climate with medium moisture supply, neither too dry nor too wet, with sufficient rainfall to support trees and woody plants.
Mesocarp The middle layer of the pericarp; e.g., the flesh of fruits such as plums and cherries.

Mesophile A "middle lover;" an organism (especially a microorganism) that grows optimally at temperatures between 20 and 50 °C. Such an organism is **mesophilic**.
Mesophily The fact of living and growing optimally at moderate temperatures.
Mesophyll (M) tissue Photosynthetic cells that are located between the arrays of vascular bundles and BS (bundle sheath) cells of a leaf.
Mesoplankton A classification of plankton according to size; those plankton of intermediate size (0.2–2 cm).
Mesopredator A predator in the middle of a food web, usually small-to medium-sized animals that are preyed on by other predators and that often benefit when apex predators decline.
Mesotrophic 1. Intermediate in production or species. 2. Specifically, describing an aquatic ecosystem characterized by moderate phytoplankton production and moderate nutrient concentrations and loadings. Compare EUTROPHIC; OLIGOTROPHIC.
Mesotrophy The fact of being intermediate in production, or the existence of species typical of intermediate-production environments.
Meta-analysis A method of summarizing outcomes across numerous studies by compiling measures of the effect of treatments; e.g., measures of the differences in biomass of primary producers in the absence or presence of predators.
Metabolic Having to do with or involved in metabolism (see next).
Metabolism The array of chemical reactions that occur in the cells of living organisms to import, transform, and transport the energy and materials needed to sustain life.
Metacommunity A set of communities; an assemblage of species in a region of space that is typically large and composed of many local communities.
Metagenomes The collective array of genomes of multiple organisms in a natural environment.
Metagenomic Involving or based on metagenomics (see next).
Metagenomics Literally, "beyond genomics;" the process of sampling the entire genetic complement of a natural environment by means of DNA isolation, sequencing, annotation, and informatics analysis. An approach to determining the genetic information of natural microbial populations, and thus of the great majority of microorganisms that cannot easily be cultured.
Metapopulation A group of local populations belonging to the same species that reconnect via regular migration to each other's habitat patches. The state of existence of most species and thought to be the original, natural state of species in general.
Metatherian A member of the infraclass of mammals that includes the marsupials.
Metazoa Those organisms whose individuals have more than one cell (multicelled animals).
Metazoan 1. having to do with or being one of the Metozoa (see previous). 2. Such an organism.
Methane clathrate Methane (CH_4) gas frozen in ice within deep submarine sedimentary pore space or permafrost.
Methanogens Anaerobic archaebacteria that convert $CO_2 + H_2$ or acetate into CH_4. Such organisms are **methanogenic**.
Methyl mercury (MHg) The form of mercury largely produced by sulfate-reducing bacteria that strongly bioaccumulate along food chains.
Microalgae See ALGAE.
Microarray A collection of microscopic DNA spots attached to a solid surface; used in the analysis of gene expression or genetic variation.
Microbe 1. A microorganism; a (usually) single-celled organism that cannot be seen with the naked eye. 2. In popular use, such an organism that causes disease.
Microbial Being, pertaining to, or caused by microbes.
Microbiology The scientific study of microorganisms.
Microclimate 1. The small-scale climate that plants, small animals, and soil microbes experience, and that differs substantially from the macroclimate reported by weather stations. This difference is related to surface warming by the sun or cooling at night, as well as wind shelter effects, and is largely driven by relief, exposure, ground cover, and plant stature. 2. In general use, any localized climate peculiar to a particular area.
Microcosm A small, representative system that has analogies to a larger system. Oceanic islands are often considered microcosms of continental areas because the composition of species on islands, and the processes of formation and decline, are analogous but occur on a much smaller scale.
Microevolution A process of evolution within species, not leading to speciation.
Microfauna Very small, typically microscopic organisms that are described as having animal-like qualities. Many inhabit water films or pore spaces in leaf litter and in the soil.
Microhabitat A small, self-contained environmental unit occupied by a specific subset of interacting species.
Microorganism An organism that can only be observed with a microscope; bacteria, archaea, protists, fungi, and small metazoans, typically smaller than 0.5 mm in equivalent diameter and with mass < 5–10 g. The category may also include viruses, though some classifications exclude these as not independently living.
Microparasite A parasite too small to be seen with the naked eye.
Micropterous Having small or shortened wings or fins.
Microsatellite See REPETITIVE DNA.
Microtidal Describing a spring tide range of less than 2 m.
Mid-domain effect A hypothesis based on random distribution of species ranges within a bounded domain, resulting in maximum species richness in the middle of the domain.
Mid-ocean ridge One of the crustal accretion boundaries between the major tectonic plates that make up the ocean crust.
Milieu souterrain superficiel (MSS) The interstitial spaces deep in the soil and mantle/bedrock interface, as found in glacially fragmented zones. Also, **mesovoid shallow stratum**.
Mimicry 1. A defensive mechanism in which organisms of two species resemble each other, ordinarily because at least one of them is distasteful or harmful and thus unattractive to predators. 2. Evolution by natural selection in which a

character is favored because it closely resembles one found in another species.

Mineralization The availability of inorganic nutrients in the microbial decomposition of organic detritus, occurring after the IMMOBILIZATION phase in which microbial demand for nutrient elements is satisfied.

Minimum viable population (MVP) The minimum size that a population must be to persist over a given time span.

Miombo A woodland habitat type widespread in south-central Africa, characterized by numerous species of the tree genera *Brachystegia* and *Isoberlinia*, which form nearly closed canopies. Fire is an annual event in this habitat, which supports relatively low populations of large mammals.

Mistletoe Woody parasitic plants of the closely related families Loranthaceae or Viscaceae with haustoria that originate as root tissue and penetrate stems or roots (in Loranthaceae) of the host plants. Also capable of photosynthesis.

Mitigation 1. Measures taken to reduce environmental impacts to the point where they will have no adverse effects. 2. Specifically, actions designed to reduce the amount that the climate will change. These actions generally involve reducing greenhouse gas emissions and sequestering carbon dioxide.

Mitigation wetland A wetland created, restored, or enhanced to replace lost wetlands.

Mitochondria (singular **mitochondrion**) Eukaryotic cellular organelles used for cellular respiration and energy production.

Mitochondrial DNA (**mtDNA** or **mDNA**) A small, maternally inherited molecule of DNA found only in the mitochondria (see previous).

Mixed intercropping See INTERCROPPING.

Mixing ratio The ratio of the concentration of a given gas to the concentration of air. It can be defined in terms of volume or mass.

Mixotrophic Feeding in both an autotrophic and a heterotrophic manner. Such an organism is a **mixotroph**.

Mixotrophy A form of nutrition involving both autotrophic (photosynthetic) and heterotrophic carbon acquisition.

Mobile element See TRANSPOSON.

Model A construct, either physical, mathematical, or computational, that is a simplification of reality developed to meet certain objectives.

Moisture deficit The difference between the existing water content of soil and the water content of the same soil at field capacity, i.e., after saturation followed by drainage.

Molecular clock A hypothesis that mutation rates and substitution rates do not vary among lineages in a tree, so that the timing of divergences can be dated from known times of divergence in the fossil record. Because rates of evolution along a lineage can vary, two different kinds of clocks (a *fixed* or a *relaxed* clock) can be used, depending on whether the rate of evolution is allowed to vary.

Molecular phylogenetics The study of the history of evolutionary relationships according to similarities and differences among (usually extant) organisms in molecular characters (such as DNA).

Molecular phylogeny A phylogeny constructed from comparisons of homologous genetic material.

Mollusk One of the Mollusca, a large phylum of invertebrates including among others the cephalopods (e.g., squid, octopus), bivalves (e.g., clams, oysters, mussels, scallops) and gastropods (snails and slugs). Also spelled **mollusc**.

Monitoring The repeated collection and analysis of observations and measurements to evaluate changes in populations of species and environmental conditions.

Monoculture 1. The agricultural practice of growing one single crop on a given field over a sequence of growing seasons. 2. The presence of a single species, or single genotype, of crop plants or other organisms.

Monoecious Having male and female flowers on the same plant.

Monogamy The reproductive pattern in which one male mates with one female exclusively. Such a pattern is **monogamous**.

Monograph effect The argument that the apparent existence of intensive evolutionary activity in a given interval actually reflects the fact that researchers have thoroughly studied a particular section of the fossil record which reveals this activity, while other such investigations elsewhere might just as well have produced the same number of previously unknown species. [From the idea that such a study produces various monographs on the subject.]

Monophyletic Describing a group in which all members are descended from a single common ancestor and all descendants of the ancestor are classified in the group. Compare PARAPHYLETIC; POLYPHYLETIC.

Monophyletic group A true, historical, evolutionary lineage consisting of an ancestor and all of its descendants; defined by shared, derived characters.

Monophyly The fact of being an evolutionary unit that includes a most recent common ancestor and all of its descendants.

Monotreme A mammal in the family Monotremata, which includes spiny anteaters and the platypus.

Monsoon (system) A wind system covering the eastern half of Asia in which winter cooling of the large landmass produces strong, stable high pressure, with clear skies and outward flow of cold, dry air, and summer warming produces low pressure, drawing wet air masses, with clouds and rain, inward from the adjacent oceans.

Montreal Protocol A treaty signed by a number of nations to curtail the production of CFCs (Chlorofluorocarbons), which are known to deplete the Earth's ozone layer.

Moor An expanse of open vegetation, dominated especially by dwarf Ericaceae and *Sphagnum* mosses, on peaty soil.

Morichal A plant community characteristic of tropical savannas; it is seasonally flooded and the presence of the palm *Mauritia flexuosa* is conspicuous.

Morphodynamics Interactions in a beach and surf zone environment between the physical structure and the water and sediment movement.

Morphological Involving or based on the structure and form of an organism.

Morphology The scientific study of the structure and form of organisms, including both outward appearance and internal features.

Morphometrics A statistical procedure by which morphological traits are quantified and analyzed.

Morphospecies A species defined on the basis of morphology alone. This criterion has been traditionally used with many eukaryotic organisms, when information about interbreeding or molecular composition was not available. In microorganisms this approach definitely underestimates real diversity.
Mosaic A spatial patch distribution of vegetation communities.
MPA Marine protected area.
MPA network A collection of individual MPAs (marine protected areas) operating cooperatively and synergistically to fulfill ecological aims more effectively and comprehensively than individual sites could alone.
MSS Milieu souterrain superficiel.
MtDNA Mitochondrial DNA.
MTE Mediterranean-type ecosystem.
Mulch A layer or covering of organic materials such as leaves, shredded bark, dried grass, compost or the like, spread around plants to enrich the soil, help retain moisture, protect against temperature extremes, and so on.
Müllerian mimicry A form of mimicry in which two or more unpalatable species resemble each other, with the effect that predators are more likely to avoid any species with this appearance. [Described by the German biologist Fritz Müller.]
Multidimensional niche A tempero-spatial region defined by meeting a set of different requirements for the viability of a particular kind of organism.
Multifunctional cropping An agricultural system that incorporates different combinations of herbaceous crops, trees, and animals within a single farm unit.
Multimodel A single integrated model that links together models utilizing different mathematical or computational approaches.
Multiple resistance The occurrence of more than one resistance mechanism in the same individual or pest population.
Multivoltine See PLURIVOLTINE.
Mushroom A large, fleshy fruiting body consisting of a cap with gills or pores on the undersurface (or sometimes flat or with teeth or folds), usually on a stalk, and producing sexual spores; used especially for members of the Basidiomycota. A poisonous mushroom is popularly called a **toadstool**.
Musth The annual reproductive period in adult male elephants, characterized by extreme aggressiveness and secretions from temporal glands.
Mutant An organism, individual, or genetic character resulting from an instance of mutation (see next).
Mutation A heritable change in the nucleotide sequence of an organism.
Mutation rate The frequency with which new mutations arise per generation.
Mutualistic A mutually beneficial association or interaction, temporary or ongoing, between or among organisms of different species.
Mutualism Describing an interaction between organisms of different species that provides survival and/or reproductive benefits to both of them.
MVP Minimum viable population.
Mycelium (plural **mycelia**) The vegetative part of a fungus, made up of a mass of branching threadlike filaments (hyphae).
Mycobiont See LICHEN.
Mycoparasite A fungus whose host is another parasite.
Mycorrhiza (plural **Mycorrhizae**) A root tip that is infected with fungi in a mutually beneficial partnership. The fungal hyphae explore large volumes of bulk soil, absorbing nutrients and transferring them to the plant; the plant supplies the fungus with the organic carbon necessary for growth and energy production. The two basic types are arbuscular mycorrhizae (endomycorrhizae), in which fungal hyphae penetrate into the plant root cells; and ectomycorrhizae, in which fungal hyphae grow between plant root cells and form a thick sheath over the root tip, but do not penetrate.
Mycotroph A plant that obtains energy through mycorrhizal associations with saprophytic or other biotrophic fungi. Such an association is **mycotrophic**.
Myrmecophily The ability to form symbiotic associations with ants. Such an organism is **myrmecophilous**.
Mysticete One of the Mysticeti, the suborder of cetaceans that includes the four families of baleen whales. Most mysticetes are quite large, including the blue whale which reaches 33 m in length and is recognized as the largest animal in the Earth's history. About 10 percent of the known modern species of marine mammals are mysticetes.
Myth A story, usually of unspecified origin and at least partially traditional, that ostensibly relates actual events to explain some practice, belief, institution, or natural phenomenon; myths provide models for human behavior and often emphasize behaviors that support conservation of biodiversity.
N_2 fixation See nitrogen fixation.
Nanoplankton A classification of plankton according to size; those plankton of very small size (2–20 mm).
Native Occurring naturally in a given area; indigenous.
Native habitat 1. The community of species and the physical environment that occurred in a region before human intervention, especially the naturally occurring vegetation. 2. The particular natural habitat of a given species.
Native species A species that evolved and is naturally distributed in a given region.
Natural capital The capacity of the natural world to provide services (ecosystem services) that contribute to human well-being. These may include provisioning services, such as food and fiber production; regulating services, such as water flow and quality, or temperature regulation of the atmosphere; cultural services, such as recreation or spiritual needs; and supporting services, such as soil formation and nutrient cycling. Fossil fuels and minerals constitute non-living natural capital, which is generally not renewable on time scales of value to society (and is relatively unaffected by changes in ecosystem status).
Natural disturbance Any relatively discrete event in time that is not directly caused by humans and that disrupts ecosystem, community, or population structure and changes resources, substrate availability, or the physical environment.
Natural enemy Any species that consumes or parasitizes another species, including predators, herbivores, parasites, pathogens, and parasitoids.

Natural experiment A change in a system, due to either natural or anthropogenic forces, that provides the basis for comparison with conditions before the change and with conditions in another setting where the change did not occur. For example, the recovery of a predator may provide a natural experiment in which conditions before and after recovery and conditions inside and outside the recovery area are compared.
Natural forest An area of land that supports a minimum of 10 percent tree cover that has arisen as a result of natural processes of establishment and succession.
Natural insurance value See INSURANCE HYPOTHESIS.
Naturalized Describing alien plants that reproduce consistently and sustain populations over many life cycles without the input of resources or direct intervention by humans; they often recruit offspring freely, but mainly near adult plants, and do not necessarily invade natural ecosystems.
Natural product A compound, organic in nature (e.g., composed of carbon, hydrogen, oxygen and nitrogen), that is produced by a living organism for a purpose other than basic life functions, and that provides some adaptive value to the producing organism.
Natural regeneration The process of replacement by natural seedlings in gaps created by the selective cutting of marketable timber.
Natural resources Components of the natural environment that have utility or value to humans. *Renewable* resources either can be replenished within a relatively short time (assuming sustainable use) such as timber or fish stocks, or they have an ongoing existence (e.g., wind energy). *Nonrenewable* resources exist only in a finite quantity (e.g., gold) or could only be replenished over geologic time spans (e.g., oil).
Natural resource(s) management The management of natural systems to maintain or provide yields of wood, water, and other resources for human use.
Natural selection The variation among individuals in their ability to survive and contribute offspring to the next generation. To the extent that the variation in offspring number is associated with genetic differences among individuals in the population, natural selection results in change in the population's genetic composition and tends to increase its average fitness.
Nature 1. The totality of the external physical world, including the plants and animals that inhabit it and the processes that occur in it, as opposed to human existence and activities. 2. The sense of this external world as an agent governing physical processes, as in "*Nature* abhors a vacuum."
Nearctic One of the major zoogeographical regions of the world. See ZOOGEOGRAPHICAL REGION.
Nearly neutral Describing a mutation whose population genetic dynamics are influenced by both genetic drift and selection.
Near-threatened Not currently meeting any of the criteria for an extinction threat category, but close to qualifying or likely to qualify soon.
Nekton Actively swimming pelagic organisms.
Neogene The Miocene and Pliocene Epochs, accorded the status of a period when the Tertiary is considered an era.
Neotenic A secondary reproductive form with juvenile morphological characters. Neotenics derive from larvae, nymphs, pseudergates, or workers through at least one special molt.
Neotropical One of the major zoogeographical regions of the world, ranging from southern Mexico through Central and South America, including the Caribbean and the tip of Florida. Also called the NEOTROPIC or NEW WORLD TROPICS. See ZOOGEOGRAPHICAL REGION.
Neritic Having to do with or living in an area of the ocean with relatively shallow waters, from the low tide mark to a depth of 200 m. This area is the **neritic zone**.
Net immobilization See IMMOBILIZATION.
Net mineralization See MINERALIZATION.
Net primary production The rate of production of biomass by plants and other primary producers such as algae; this forms the basis for all food webs. Also called **net primary productivity**.
Neural crest An embryonic tissue in vertebrates intermediate between the neurectoderm and ectoderm, with cells migrating widely to their final destination. This tissue gives rise to anterior skeletal elements, many portions of the future head and pharynx, and all pigment cells. Also, MESECTODERM.
Neurectoderm An embryonic tissue that gives rise to the central tube of the nervous system.
Neutral mutation A mutation whose effect on fitness is either non-existent or so small that its fate is controlled by genetic drift rather than by selection.
Neutral theory The principle that the majority of nucleotide substitutions result from the random fixation of neutral or nearly neutral mutations.
New production Primary production in the ocean maintained by assimilation of new sources of nitrogen (N) to the euphotic zone, such as nitrate (NO_3^-) or N_2. Compare REGENERATED PRODUCTION.
New World Tropics see NEOTROPICAL.
NGO Nongovernmental organization.
Niche The unique position of a particular species in an ecosystem in relation to other species and with respect to its resource use, habitat requirement, and other functions within the larger community.
Niche complementarity The differential acquisition and use of resources by different species; niches of different species differ which results in more complete utilization of resources in spatially or temporally complex environments.
Niche differentiation Differences in the morphology, physiology, or behavior of species that can influence their abundances, dynamics, and interactions with other species, including the ability of various competing species to coexist.
Niche dimensions Ranges of values of environmental measurements in an ecological niche. A range of temperatures, salinities, or oxygen concentrations may be niche dimensions for a population of fish.
Niche overlap The proportion of available resources that are shared by two species, especially in the context of a single resource that limits population growth.
Nitrification The step in the nitrogen cycle in which ammonia is oxidized and converted to nitrite and then oxidized again to form nitrate; a biogeochemical process mediated by soil microbes.
Nitrogenase A metalloenzyme complex that catalyzes the process of nitrogen fixation (see below).

Nitrogen deposition The process by which reactive forms of nitrogen are deposited to the Earth's surface through either wet or dry deposition.
Nitrogen fixation The reduction of atmospheric dinitrogen (N_2) to ammonia (NH_3) or other organic or inorganic compounds by bacteria, lightning, or photochemistry.
Nitrogen saturation Nitrogen supply in excess of the capacity of the ecosystem to retain it.
Nitrophytic Describing species of plants that either tolerate or require high levels of nutrients, especially nitrogen. Such an organism is a **nitrophyte**.
Node A branching point on a cladogram corresponding to a hypothetical common ancestor.
Non-avian dinosaurs The Dinosauria excluding modern birds (Aves); i.e., the extinct forms popularly considered to be the only dinosaurs.
Nonexcludable See PUBLIC GOOD.
Nongovernmental organization (NGO) An organization that is not an agency or part of a government, typically one that is not-for-profit and not owned by individuals.
Nonindigenous 1. Not native; not originating in the site that it now occupies. 2. Specifically, describing crop plants that did not originate in the range where they are now cultivated. Also, **nonnative**.
Nonpoint source (NPS) A diffuse source of pollution not attributable to any single specific discharge (e.g., agricultural runoff, urban runoff, or atmospheric deposition). Contrasted with POINT SOURCE.
Non-renewable Describing a resource that cannot be grown or produced at a level which over time will sustain its present consumption rate; for example, because it exists only in a finite quantity (e.g., gold) or it could only be replenished over geologic time spans (e.g., oil). Contrasted with RENEWABLE.
Non-renewable energy Those forms of energy whose transformation consumes the energy source. The major ones are the fossil fuels (coal, oil, and natural gas) and nuclear power (because it requires the mineral uranium). Compare RENEWABLE ENERGY.
Nonrival See PUBLIC GOOD.
Non-structural flood management Flood-risk management approaches that do not depend on controlling water with engineered structures. Examples include land-use planning, building codes, insurance, and use of the natural and beneficial functions of floodplains, including storage and conveyance of flood waters.
Nonsynonymous mutation A nucleotide change in a protein coding region that changes the encoded amino acid.
Non-use ecosystem services Benefits that are derived from ecosystems without actually using them, such as the benefit derived simply from knowing a certain ecosystem exists (existence value).
Nonuse values Values ascribed to the natural environment that are independent of any human interaction with it; for example, an individual valuing the pure existence of a natural habitat or ecosystem or wanting to "bequeath" it to future generations. Compare DIRECT USE VALUES; INDIRECT USE VALUES.
North Atlantic Oscillation (NAO) The difference in atmospheric pressure between Ponta Delgada, Azores, and Stykkisholmur, Iceland. The variations in the NAO are usually associated with a positive or negative phase related to changes in the direction and strength of the westerly wind as well as in sea surface temperature. During a positive phase, winters over Scandinavia are warmer and the opposite for a negative phase. Recently, the fluctuations observed in the NAO have been related to changes in ecosystem processes.
No-take area A classification for a marine area that is permanently or temporarily completely closed to any form of extraction, and where no disturbance of any kind is allowed.
Nothofagus A genus of Southern Hemisphere trees with a classic Gondwanic (see) distribution in southern South America, southeastern Australia, New Zealand, New Caledonia, and New Guinea.
Notochord A stiff, flexible, longitudinal rod running along the mid-dorsal portion of the chordate body. It is situated dorsal to the coelom and ventral to the central tube of the nervous system.
NPS Nonpoint source.
Nuchal organ Any of various sensory organs with nerves coming from the posterior part of the brain or from the nerve ring, usually present as ciliated pits or short ridges at the posterior end of the prostomium. Found in most polychaete worms and also present in the sipunculid worms.
Nucleotide A subunit of DNA and RNA, composed of a ringed five-carbon sugar, a ringed nitrogen-rich base, and phosphates. Nucleotides are often referred to as base pairs because individual types form complementary hydrogen bonds (G-C and A-T in DNA, G-C, and A-U in RNA) to make double-stranded DNA and RNA molecules.
Nucleus 1. The compartment of a cell in which DNA is stored on chromosomes; it functions as the central control unit of the cell. 2. The dense region at the center of an atom, consisting of protons and neutrons. **3**. Any crucial central part around which other parts are grouped.
NUE Nitrogen-use efficiency; a measure of photosynthesis or growth relative to the nitrogen content of the leaves or plant.
Nunatak An isolated ice-free summit of a mountain whose bulk is permanently below the surface level of an ice sheet. [From the Inuit term for this feature.]
Nurse plant A plant that shelters and facilitates the growth of others.
Nutrient Any of the various inorganic chemicals (particularly nitrogen, phosphorus, and silicon) required for the survival and growth of animals and plants, including crops and phytoplankton.
Nutrient cycle The repeated pathway of mineral elements, such as carbon, nitrogen, phosphorus, and water, from the environment through organisms and back into the environment.
Nutrient-enriched Having elevated concentrations of nitrogen and phosphorus nutrients, especially in an aquatic ecosystem. This condition is **nutrient enrichment**.
Nutrient-limited Having growth limited by the relative amount of a certain nutrient, or by the proportion of two nutrients to each other. This condition is **nutrient limitation**.
Nutrient-saturated Having a nutrient or nutrients available well in excess of the amount required for growth. This condition is **nutrient saturation**.
Nutrient stoichiometry 1. The study of changes in the relative proportions of critical nutrients available in the environment, relative to differences in the allocation of these

elements in organisms. 2. The study of the relative availability of critical elements in ecosystems, as both an influence on and an overall result of interactions among biota and system biogeochemistry.

Nutrient uptake capacity The instantaneous rate of nutrient acquisition, usually measured in brief (1–2 h) incubations. Uptake capacity reflects the abundance of transport sites on the root cell membranes and their affinity for nutrient ions.

Nutritionalism The view that bottom-up forces (i.e., nutrients) regulate populations.

Nymph An immature individual that is on the developmental pathway to the imago and that possesses external wing buds.

Obligate Obliged or required; able to function in only one way; e.g., a parasite that cannot live without a host; bacteria that can only live in an aerobic environment. Also, **obligatory**. Compare FACULTATIVE.

Obligate carnivore A carnivorous animal that eats only meat and not non-animal food.

Obligate epiphyte A plant that always grows on another plant for structural support, but derives no nutrients from the host.

Ocean acidification Ongoing changes in carbonate chemistry of the Earth's oceans (e.g., decrease in pH and decrease in carbonate ions), caused by their uptake of anthropogenic carbon dioxide from the atmosphere.

Ocean observatory A collection of airborne and in-water sensors for characterizing oceanic chemical, physical, and biological parameters that may vary over time.

Odontoceti The suborder of the cetaceans that includes the ten families of toothed whales, including sperm whales, beaked whales, dolphins, porpoises, belugas, narwhals, and river dolphins. Approximately half of the known modern species of marine mammals are odontocetes.

ODP Ozone depletion potential.

Offset activities The set of activities identified to achieve no net loss or a net gain of biodiversity in the specific context of the development project concerned.

Old-growth (forest) A forest undergoing a late stage of succession that is relatively stable with regard to forest structure, ecosystem function, and species composition.

Old World Tropics See PALEOTROPICS.

Oligonucleotide A short, single-stranded nucleic acid molecule either obtained from an organism or synthesized chemically.

Oligotrophic Describing an ecosystem or water mass that is low in nutrients and generally characterized by low-standing stocks of living biomass. Compare EUTROPHIC; MESOTROPHIC.

Oligotrophy The fact of being low in production, or the existence of species typical of low-production environments.

Ombrotrophic Describing ecosystems or plant species only receiving nutrients in precipitation. This condition is **ombrotrophy**.

Omnivorous Describing a consumer that feeds on various food sources; e.g., a predator with a diet of plants and other animals as a primary food source. Such an animal is an **omnivore**.

Omnivory The fact of feeding at more than one trophic level, as when a predator consumes not only prey species but also herbivores and other predators.

Ontogenic Having to do with or being part of ontogeny (see next).

Ontogeny The sequence of embryonic and postembryonic changes in the characters of an organism in the course of its life. Also, **ontogenesis**.

Open access resource 1. A resource that is nonexcludable; i.e., it can be exploited by any person, regardless of the consequences of that exploitation for other would-be users. 2. A resource for which property rights are not recognized or clearly defined.

Open community A community that receives immigrants from external sources and may export emigrants as well.

Operational taxonomic unit (OTU) A group of organisms regarded as being distinct from other groups, based on any clearly defined set of variables.

Opportunistic species A species typical of transient, unstable, unpredictable, frequently disturbed, or periodically extreme environments, usually having strong dispersal abilities and faster growth, smaller size, and shorter life spans than potential competitors.

Opportunity costs Costs of foregone opportunities; i.e., a measure of what could have been gained by the next-best use of a resource had it not been put to the current use. In terrestrial protected areas where extractive uses are forbidden, the opportunity cost represents the highest-value extractive use for that land. It is important to include opportunity costs to track the full set of consequences of conservation planning.

Option value The potential benefits of a resource not derived from actual use, expressing a preference for conservation of the resource against some probability that it can be used at a later date.

Organelles Membrane-bound structures within eukaryotic cells that carry out specific functions and often contain their own DNA; typical organelles are mitochondria and chloroplasts.

Organic 1. Relating to or coming from living beings as opposed to inanimate matter. 2. Describing farming practices (**organic agriculture** or **farming**) that rely on biological inputs and diversity for soil fertility and pest and disease suppression; **organic farms** that are certified by government policies or private organizations are not allowed to use synthetic pesticides or fertilizers.

Organismal Having to do with living or formerly living beings (organisms).

Organismal diversity The number and relative abundance of all species of organisms living in a given area.

Ornithischian One of the Ornithischia, the so-called bird-hipped dinosaurs such as horned and duck-billed dinosaurs.

Orobiome A mountain range characterized by a particular climatic pattern and a characteristic sequence of vegetation zones.

Orogenesis The process of formation of mountains.

Orographic clouds Clouds that are formed as moist air rises over mountains.

Orthophyllous Pollinated by birds.

OTU Operational taxonomic unit.

Outbreeding A mating system in which individuals breed with other individuals that are not closely related to them.

Outgroup A species or other taxonomic group chosen to establish the root of any phylogeny.

Outpost An individual, isolated tree or small group of trees appearing above the tree line.
Output environment A collective term for all energy and materials moving out of a given system.
Overcompensatory growth In grazed plants, the reaction to tissue removal by enhanced primary production compared to that in undefoliated controls.
Overexploitation The harvesting of a natural resource, such as fish or timber, at a rate more rapidly than it can be naturally replenished; the opposite of sustainable use.
Overfishing The process of extracting marine organisms faster than they can reproduce.
Overgraze 1. To carry on a process of overgrazing; consume forage at a level that is not sustainable. 2. The fact or process of doing this.
Overgrazing The consumption of forage to the extent that declines in productivity or desirable species composition are probable (i.e., degradation). It represents excessive use in terms of the amount, duration, and frequency of plant utilization.
Oviparous 1. Describing reproduction in which the eggs hatch outside the mother's body. 2. Describing an organism with this mode of reproduction; e.g., birds. The fact of reproducing in this way is OVIVIPARITY. Compare OVOVIVIPAROUS; VIVIPAROUS.
Oviposition The fact or process of laying eggs.
Ovipositor A modified appendage in some animals used for egg-laying (e.g., wasps) and also for other purposes in some cases.
Ovoviviparous 1. Describing reproduction in which the embryos develop within eggs retained by the mother within her body until they hatch. 2. Describing an organism with this mode of reproduction; e.g., some fish and reptiles. The fact of reproducing in this way is OVOVIVIPARITY. Compare OVIPAROUS; VIVIPAROUS.
Oxic 1. Having oxygen. 2. Specifically, describing an environment or habitat in which oxygen is present.
Oxidizing capacity A self-cleansing ability of the atmosphere through oxidative reactions.
Oxygen isotopic composition The ratio of common isotopes of oxygen (16O and 18O) analyzed in a mass spectrometer and reported in delta notation (d18O) relative to a standard; reported in parts per thousand and used as a proxy for paleo temperature and global ice volume.
Ozone A form of oxygen in which three atoms of oxygen occur together, extremely important to life on Earth because of its absorption of solar ultraviolet radiation in the stratosphere's **ozone layer**. Ozone is also a greenhouse gas.
Ozone depletion A decline in the total volume of the Earth's ozone layer, observed since the 1970 s and attributed to the presence there of certain industrial chemicals (e.g., CFCs) that are now generally banned.
Ozone depletion potential (ODP) The relative amount of decline in the total volume of the ozone layer that a given substance can potentially cause, based on a scale in which trichlorofluoromethane (a well-known depleting agent) has a value of 1.0.
Pacific Decadal Oscillation (PDO) A long-term El Niño-like pattern of Pacific climate variability. The climate oscillations ENSO (El Niño Southern Oscillation) and PDO have similar spatial climate fingerprints, but very different behavior in time; e.g., 20th century PDO events persisted for 20 to 30 years, while typical ENSO events persisted for 6 to 18 months.
Pacific salmon Any of several species in the genus *Oncorhynchus* that always die after spawning (and hence are semelparous). Five Pacific salmon species occur in North America: Chinook, coho, sockeye, chum, and pink. Western trout in the genus *Oncrorhynchus* are closely related to Pacific salmon; however, like the Atlantic salmon (*Salmo salar*), these species can spawn in more than one year.
Paedomorphosis Reproduction while retaining at least some larval characteristics.
Palearctic One of the major zoogeographical regions of the world. See ZOOGEOGRAPHICAL REGION.
Paleo- A prefix meaning very old; ancient; used to refer to ancient time periods.
Paleoclimatology The study of ancient climates, on the basis of evidence from fossils and other traces left in the geological record.
Paleotropics Tropical regions of the Eastern Hemisphere extending from Africa through south and southeast Asia into the southwest Pacific. Also known as the Old World Tropics.
Palynology The study of pollen and spores.
Palynomorphs Pollen and spores produced by plants.
Pampa(s) A region of temperate South America, west of the Andes in Argentina. It contains several ecosystem types, including temperate grasslands, dry forest, and xeric shrublands.
Panbiogeography The examination of biogeographical distributions and relationships on a worldwide scale.
Pantanal The largest wetland of South America, drained by the Paraguay River and its tributaries.
Páramo 1. An ecosystem of the high Neotropical mountains, found in South America above the tree line in the northern Andean mountains of Colombia, Venezuela, Ecuador, Peru, and Bolivia. The dominant vegetation is similar to an alpine meadow or grassland; cacti and giant-rosette plants are conspicuous. 2. Any such cold, humid landscape located above the tree line.
Parapatric Describing taxonomic entities whose geographic ranges are distinct but adjacent to each other.
Parapatry The relationship of organisms whose ranges do not significantly overlap but are adjacent to each other.
Paraphyletic Describing a group that includes a common ancestor and some, but not all, of its descendants. Compare MONOPHYLETIC; POLYPHYLETIC.
Paraphyletic group A group of taxa that includes some, but not all, of the descendants of the most recent common ancestor for the group.
Paraphyly The fact of being an evolutionary unit that includes a most recent common ancestor and some, but not all, all of its descendants.
Parapodia (singular **parapodium**) Segmentally arranged outpockets from the body wall of certain invertebrates, usually divided into two branches (rami), which are the dorsal notopodium and the ventral neuropodium. Present in most polychaete species, but extremely variably developed and sometimes entirely absent.
Parasitic Being, having to do with, or caused by a parasite.

Parasite An organism that obtains its nutrition from a living host (and usually lives inside or on it), and in so doing harms the host.
Parasitism A close association of two organisms in which one, the parasite, depends on the other (the host), deriving some benefit from it and damaging it.
Parasitoid An organism that spends a significant portion of its life history attached to or within a single host organism; unlike a true parasite, it ultimately sterilizes or kills the host.
Parataxonomist A lay person trained to collect and carry out preliminary identification of botanical and zoological specimens that will be used for taxonomic purposes.
Pareto efficiency or optimality An economic equilibrium in which any change to the system will decrease the economic well-being of at least one participant; such a system is **Pareto efficient**. If a change can be made to an economic system that will benefit at least one individual without harming anyone else, that is a **Pareto improvement**. [A concept introduced by the Italian economist Vilfredo Pareto.] See also KALDOR–HICKS EFFICIENCY.
Pareto principle The so-called 80–20 rule; the idea that for many events and conditions, 20 percent of the agents produce 80 per cent of the effects or results. Examples might be 20 percent of a given area containing 80 percent of its total biodiversity, or 20 percent of the residences in a community occupying 80 percent of the total land cover. [Based on Vilfredo Pareto's observation that 80 percent of the land in Italy was owned by 20 percent of the people.]
Parr Older juvenile salmon that are distinguished by **parr marks**; i.e., prominent oval spots on their sides.
Parsimony The general scientific principle that given alternative explanations or hypotheses for a set of observations or data, the most corroborated is the **parsimonious** one; i.e., the one that requires the fewest ancillary or additional hypotheses.
Parthenogenesis Reproduction in which eggs are not fertilized by males.
Passive crown fire A term for a wide range of crown fire behavior, from torching of individual crowns to burning of dense patches of vegetation.
Passive recovery The process of allowing a system to recover on its own without intervention beyond removing the disturbance. Similarly, **passive restoration**.
Pastoral(ist) Having to do with or practicing pastoralism.
Pastoralism 1. The agricultural practice of raising livestock. 2. A traditional, often nomadic economic and cultural system based on the raising of livestock. **3**. Traditional agricultural life and work in general, or a literary or artistic description of this.
Pasture Lands in which the native grasses and other vegetation have been removed in favor of cultivated grasses or other forage plants to be used by grazing domestic animals.
Patagium The skin that stretches across the arms and legs of flying and gliding mammals.
Patch A relatively homogenous area within a larger landscape that differs markedly from its surroundings.
Patchiness Variation from place to place (or time to time) in the abundances of animals or plants, caused by the interaction of numerous processes.
Pathogen The causative agent of an infectious disease, typically a virus, bacterium, protozoan, fungus, or multicellular parasite. Such an agent is **pathogenic**.
Payments for ecosystem services (PES) Financial rewards for individuals who protect habitats so that the provision of natural goods and services can continue; payments may be made by private parties that benefit from the delivery of those ecosystem goods and services, or by a governmental or other agency. **Payments for watershed services** is a subset of PES that involves a similar financial transaction, but with the focus on watershed-based hydrologic services.
PCR Polymerase chain reaction.
Peat 1. A type of soil formed from the accumulation of the remains of dead plants, with high organic matter content (minimally 20% and as high as 90% by dry weight) and depth greater than 30 to 40 cm. Peat forms in some wetlands because anoxic conditions, low pH, low temperatures, and short growing seasons, or plant tissues highly resistant to decay, prevent rates of decomposition from keeping up with rates of organic matter production. 2. Peat fuel (see next).
Peat fuel Dried peat biomass used as a fuel; a traditional fuel source in various northern regions; e.g., Ireland.
Peatland A wetland in which dead organic matter accumulates to form peat more than 30 to 40 cm deep; this typically includes bogs, poor fens, and rich fens but some swamps also occur on peat.
Pedipalps The second pair of pre-oral appendages in spiders and other arachnids. They are multi-segmented and primitively leg-like. They may be raptorial (grasping) or sensory (like antennae) or used as walking legs.
Pelagic 1. Located in or relating to the water column in aquatic environments. 2. The open-water part of the aquatic environment that is far from the shore and the bottom bed.
Pelagic organism A free-swimming (nekton) or floating (plankton) organism that lives exclusively in the water column.
Pelagic zone The open-water portion of the ocean, a lake, or another body of water, beyond the littoral zone.
Penetrometer A device used to test the compressive strength of soil, based on the energy required to push a probe of defined size and shape into the soil.
PEP carboxylase Phosphoenolpyruvate carboxylase; the initial carboxylation enzyme in C_4 photosynthesis.
Peptide A compound composed of several amino acids that are linked together by amide bonds.
Perennating structures The tissue that carries a plant into a new growing season; e.g., buds of trees, shrubs, and so on; bulbs of some plants such as tulips; or seeds of annuals.
Perfect competition The ideal form of a market economy, in which all goods are owned by perfectly rational, perfectly informed individuals, all goods can be bought and sold in markets, and no single participant can determine the price at which transactions take place. Such an economy is **perfectly competitive** and is said to have PARETO EFFICIENCY (see).
Periodic parasite A parasite that visits a host at intervals.
Periphyton Bacteria, fungi, algae, and sessile microfauna growing attached to substrata (sediments, rock, plants, animals, sand).
Peristomium In annelid worms, a region around the mouth of the larvae; if distinct in adults it may carry peristomial cirri.

Permafrost The phenomenon of ground materials (e.g., soil and bedrock) that are at or below 0–1 °C for two or more years. Usually, but not always, any water present is in the solid state. The Arctic is characterized by the presence of large, continuous areas of permafrost that have the form of lower soil layers permanently frozen with a shallow active layer that freezes and thaws each year and accommodates below-ground biological activity.
Permanence A property of communities that ensures the long-term coexistence of species because community trajectories (variation in numbers through time) have no species approaching very low numbers.
Permanent parasite A parasite associated with a host for long periods.
Persistence The sustained existence of species or other elements of biodiversity.
Perturbation A temporary change in one or more dynamical variables or parameters of an ecosystem or other dynamical system, due to external factors.
PES Payments for ecosystem services.
Pesticide A chemical substance used for killing, preventing, controlling, or mitigating a pest organism.
Pesticide resistance The inherited ability of a pest to survive and reproduce following exposure to a dose of pesticide normally expected to be lethal to individuals of this species.
Petaloid Describing flowers with petals present, and typically showy.
pH The free hydrogen ion concentration of an aqueous solution, measured on a logarithmic scale and used to express the acidity or alkalinity of the solution. At 25° C a neutral solution, such as pure water, has a pH value of 7. A solution with a pH below 7 is considered to be acidic and one above 7 is considered to be alkaline. Because pH is a logarithmic scale, the amount of strong acid required to decrease the pH by one unit value increases greatly. Water with a pH of 5 has 100 times the hydrogen ion concentration of a pH 7; a pH of 4 has 10 times the hydrogen ion concentration of pH 5, or 1000 times the hydrogen ion concentration of a pH 7 solution. [Said to be a shortened form of Potential (or Power) of hydrogen.]
Phagotroph An organism that feeds by ingesting solid food particles (e.g., bacteria). Such an organism is **phagotrophic**.
Phagotrophy The fact or process of feeding on particulate organic matter.
Phanerogam A plant with conspicuous reproductive organs (flowers); reproduction takes place by seeds.
Phanerozoic The geological interval of abundant animal fossils, beginning approximately 545 million years ago.
Pharynx An organ in animals, serving as part of the respiratory system. In fish it is the anterior portion of the alimentary canal, characterized by lateral buds that provide skeletal support for the gill region. In humans it is the part of the throat below the mouth and nasal cavity, and above the esophagus and larynx.
Phenetic Describing a taxonomic classification or grouping based purely on overall similarity.
Phenetic biodiversity A characterization of a biota that relates to variation in phenotypic characteristics (traits) of taxa, and estimated by components that reflect the size of the phenotypic hypervolume defined by constituent taxa, or the dispersion of phenotypes within that hypervolume.
Pheneticist A scientist who practices or studies the discipline of phenetics (see next).
Phenetics The study of phenotypes, especially the grouping of organisms into taxa on the basis of estimates of similarity. Pheneticists use matrices of overall similarity rather than parsimony to construct a phenogram (see next) as an estimate of phylogeny.
Phenogram A branching diagram showing overall levels of phenetic resemblance rather than cladogenesis.
Phenological Having to do with or based on phenology (see below).
Phenological shift A change over years in the mean of the phenological value of a trait within a population.
Phenology The study of the timing of recurring natural events, such as leafing or flowering, the initiation of reproduction, or the return date of migrant birds.
Phenomenological model A model that relates observable variables without postulating the underlying mechanisms (physical, biological, and so on). For example, the species–area relationship is a phenomenological model because it does not explicitly state the mechanisms leading to the relationship between the number of species and the area.
Phenophase A given phenological event that is being recorded, such as first leafing.
Phenotype The observable characteristics or traits of an organism, including its appearance and behavior. Compare GENOTYPE.
Phenotypic Relating to the observable characteristics of an organism.
Phenotypic plasticity The ability of an organism to change its phenotype in response to changes in the environment.
pH number or value See pH.
Phorb Another spelling of FORB.
Phoresis A method of long-range dispersal in which the dispersing animal attaches itself to another animal (e.g., beetle, wasp, or bird) that carries the disperser along with it until the disperser drops off or disembarks. Also, **phoresy**.
Phoretic having to do with or practicing phoresis (see previous).
Photic zone Another term for the EUPHOTIC ZONE.
Photoautotroph An organism able to synthesize organic compounds from water and inorganic nutrients, using the energy in photons of light.
Photoautotrophic Using light as an energy source for synthesis of organic matter from inorganic precursors.
Photoautotrophy A type of autotrophy (self-feeding) in which organisms gather light energy in order to reduce carbon dioxide to organic carbon; characteristic of green plants, most algae, and some prokaryotes.
Photochemical source (or **sink**) The production (or loss) of an atmospheric gas involving photodissociation or chemical reactions.
Photodissociation The destruction of a molecule through absorption of solar radiation and subsequent breaking of one or more chemical bonds.
Photolithoautotrophy A form of metabolism that depends on light as an energy source, inorganic compounds (e.g., H_2O, H_2S) for reducing equivalents, and CO_2 as a source of carbon.

Photoorganoheterotrophy A form of metabolism that utilizes light as a source of energy and organic compounds as sources of both reducing power and carbon.
Photoperiod The length of the daylight period. Photoperiod is sensed by green tissues, and is involved in phenological events such as leaf abscission in autumn.
Photoperiodism The fact of reacting physiologically to changes in the duration of the daylight period.
Photorespiration A biochemical process in which O_2 is assimilated during the oxygenation of Rubisco (Ribulose-1,5-bisphosphate carboxylase oxygenase), and CO_2 is given off in the metabolism of the products of Rubisco oxygenation.
Photosynthesis A fundamental chemical process in which green plants (and blue-green algae) utilize the energy of sunlight and other light to convert carbon dioxide and water into carbohydrates, with chlorophyll acting as the energy converter. This releases oxygen and is the major source of atmospheric oxygen. Photosynthesis provides green plants with their energy requirements, and allows other organisms to obtain nutrients from these plants, either directly or indirectly (by consuming organisms that consume green plants).
Photosynthetic Relating to or involved in a process of photosynthesis (see previous).
Phototroph An organism utilizing the energy of sunlight or other light for growth.
Phototrophic Describing energy metabolism based on light energy.
Phototrophy The ability to obtain nutrition or energy directly from sunlight and other light.
Phrygana Dwarf shrubland of the eastern Mediterranean Basin, characterized by a dominance of species with seasonal leaf dimorphism.
Phycobiont See LICHEN.
Phylesis A line or lines of descent between ancestors and descendants.
Phyllopod A leaf-like appendage.
Phylogenetic Having to do with or based on phylogeny (see below).
Phylogenetic diversity Adjusted diversity measures that take into account the degree of relatedness among a set of species in an assemblage. Other things being equal, an assemblage of closely related species is less phylogenetically diverse than a set of distantly related species.
Phylogenetics The study of evolutionary relatedness among various groups of organisms (e.g., species or populations).
Phylogenetic tree See PHYLOGENY (next).
Phylogeny The evolutionary relationships among taxa (groups of related organisms), often portrayed with some kind of tree-like branching diagram (phylogenetic tree), with the branches representing speciation events and the lengths of branches representing time since divergence.
Phylogeography Studies concerned with the principles and processes governing the geographic distributions of genealogical lineages, especially within and among closely related species.
Phylogram A cladogram (see), especially one interpreted to show terminal taxa and ancestral nodes (intermediate specificity between a generalized cladogram and specific phylogenetic tree).
Phylotypes Molecularly differentiated taxa.
Phylum The highest level of taxonomic division in the animal kingdom, followed in descending order by class, order, family, genus, and species.
Physiognomy The general appearance of a given area, especially a natural area. For example, any desert has a certain recognizable physiognomy, regardless of species composition.
Physiography The landforms that lend shape and character to the continental landscape, for example, the configuration of mountains and drainage basins.
Phytochorion (plural **phytochoria**) A region within which a substantial proportion of the flora is endemic.
Phytophagous Feeding on plants; herbivorous.
Phytophagy Plant feeding; herbivory.
Phytoplankton Plant plankton; i.e., usually single-celled photosynthetic plankton, largely algae and cyanobacteria.
Phytotoxic Harmful to plants.
Picophytoplankton The smallest ($<$ 2 mm) size class of photoautotrophic plankton i.e., the picoplankton (see next).
Picoplankton 1. A classification of plankton according to size; those plankton of extremely small size (0.2–2 mm). 2. The fraction of aquatic biomass in the size fraction that passes through 3.0 and 0.8 μm filters, and is retained on a 0.1 μm filter.
Pinniped A member of the Pinnipedia, marine mammals with fin-like limbs including the seals, sea lions, fur seals, and walrus. Approximately one-quarter of the known modern species of marine mammals are pinnipeds. Pinnipeds are in the mammalian order Carnivora.
Pioneer One of the first groups of species to colonize a newly formed or denuded habitat.
Piscivore A predator that consumes fish in aquatic habitats.
Placenta In most mammals, the organ providing nourishment to the developing fetus via the umbilical cord.
Placental Having a placenta; see EUTHERIAN.
Planktivore A predator that consumes zooplankton in aquatic habitats.
Plankton Small organisms with no or limited powers of locomotion that float freely in the water column of lakes or the ocean and are largely dispersed by turbulence and other water movements. Phytoplankton (plant plankton) are plankton with photosynthetic pigments and zooplankton are the animals of the plankton.
Planktonic Having to do with or being one of the many types of small organisms that float freely in the water column.
Planktotrophic Feeding on plankton to survive and grow. This feeding pattern is **plankotrophy**.
Planned biodiversity Crops and livestock purposefully introduced and maintained in an agroecosystem by humans, as opposed to the associated natural biodiversity that already exists there (unplanned biodiversity).
Plantation An area of land that supports planted forest or food or fiber crops, usually for commercial exploitation.
Plantation monoculture A plantation forest involving a single species. The original biodiversity at the site is not recovered, though the protective function and many of the original ecological services may be re-established.
Plant breeding The systematic process of genetic improvement of plants for food and agricultural uses.

Plantigrade 1. Walking on the soles of the feet. 2. An organism that walks in this manner; e.g., humans, bears, mice. Compare DIGITIGRADE, UNGULIGRADE.
Planula (plural **planulae**) The ciliated planktonic larval stage of a coral.
Plasmid A piece of DNA (usually circular) which can replicate independently of the chromosome of a cell and which codes for supplementary (noncore) functions.
Plasticity The ability of a plant to respond to temporal changes or spatial variation in environmental conditions by altering the size or the distribution of its parts. These are phenotypic rather than genetic changes.
Plastron 1. In aquatic insects, a set of body structures that trap a thin layer of air against the body; oxygen from the surrounding water is added by means of diffusion to the same extent that oxygen is withdrawn by breathing. 2. The flat lower portion of the shell of a turtle.
Plate tectonics 1. A modern geological theory of tectonic activity, according to which the earth's crust is divided into a small number of large, rigid plates whose independent movements relative to one another cause deformation, volcanism, and seismic activity along their margins. 2. The study of the movement of these plates and of how this process has been involved in the evolution of Earth's crust.
Pleiotropic Describing a gene that has more than one independent phenotypic effect.
Pleiotropy The fact of one gene affecting more than one trait.
Pleistocene The geologic period from 2 million to 10,000 years before the present, which was characterized by a series of glacial advancements (ice ages) separated by warmer interglacial periods.
Pleopod An abdominal appendage in crustaceans.
Plesiomorphic Describing an ancestral or primitive character, relative to sister group.
Plesiomorphy An apomorphic character or character state that specifies a more inclusive group than that under consideration.
Pliocene An epoch within the Cenozoic, the most recent prior to the Quaternary, from about 5.3 to 2.6 million years ago. The Pliocene is characterized by largely modern flora and fauna, and is the most recent epoch to have experienced extended periods globally warmer than the present.
Plow horizon The homogenous soil layer of an agricultural field, typically at 0–20 cm depth, that results from the field being plowed; designated as the "Ap" horizon in soil morphology. See also SOIL HORIZON.
Plume prospecting The process of detecting chemical and physical anomalies in hydrothermal plumes to locate hydrothermal vents.
Plurivoltine Describing species with several generations of offspring per year. Also, MULTIVOLTINE.
Pneumatophores Roots growing vertically from underground roots that spread laterally from the main stem, occurring in some genera of mangrove, such as *Avicennia* and *Sonneratia*. They typically stand 10–20 cm above the soil surface, enabling gas exchange to take place with the underground roots.
Podzol A soil type highly characteristic of boreal forests and developed as a consequence of podzolization (see next).
Podzolization The process of acid leaching in soil, in which clay, organic particles, and mineral ions (primarily iron and aluminum) are carried downwards and deposited in the B soil horizon, leaving an impoverished and leached A horizon above. This occurs as a consequence of low temperatures and precipitation in excess of the needs of evapotranspiration. See also SOIL HORIZON.
Poikilohydry A condition in certain organisms, such as some aquatic algae, in which their internal water balance varies with changes in ambient humidity; i.e., they are not able to compensate for fluctuating humidity. Contrasted with HOMOIOHYDRY.
Point source A specific, readily identifiable input of pollution, such as when treated wastes are discharged from a municipal, industrial, or agricultural facility to receiving waters through a pipe or a drain. Contrasted with NONPOINT SOURCE.
Poisson distribution 1. A discrete probability distribution used to model the number of events of a given type occurring in a specific time and/or space. 2. In this context, the probability of distribution of numbers of organisms per area if the organisms are distributed completely at random in the space; e.g., the number of prairie dogs in a square mile of prairie. [Introduced by the French mathematician Siméon Poisson.]
Polarity The relative occurrence of derived versus ancestral character states.
Pollard A tree repeatedly cut at about 6–10 ft above ground, to produce successive crops of wood.
Pollution The introduction into air, water, or soil of contaminant substances in quantities that are threatening to living resources, biological processes, and/or human health and activities.
Polyandrous Describing a female that has more than one male mate.
Polyandry A mating system in which a female mates with more than one male.
Polyculture 1. The agricultural practice of growing two or more crops either simultaneously or in sequence on the same piece of land. 2. The presence of a diversity of species, or genotypes, of crop plants or other organisms.
Polygamous Reproducing with several different mates.
Polygamy A reproductive pattern in which males and females both have several different mates.
Polygynous Describing a male that has more than one female mate.
Polygyny A mating system in which a male mates with more than one female.
Polymerase chain reaction (PCR) An enzymatic technique for selectively copying (amplifying) a specific segment of DNA across several orders of magnitude. A common variation of this is **quantitative PCR (qPCR)**, wherein the progression of the amplification reaction is recorded optically in real time, providing a means for rapidly estimating the abundance of a particular sequence of DNA in a given sample.
Polymorphic Having to do with or showing a genetic difference between two or more individuals of the same species.
Polymorphism The existence at intermediate frequencies of two or more variants at a given gene locus within a population.
Polyp The basic unit of the coral animal, consisting of a simple tubular structure with a mouth and ring of tentacles at one end. The polyp sits in a skeletal cup called the **corallite**.
Polypeptide A single chain of amino acids.

Polyphyletic Describing a group of animals that, although grouped together in a phylogeny or evolutionary tree, do not share a common ancestor. Compare MONOPHYLETIC; PARAPHYLETIC.
Polyphyletic group A taxon for which all included species (or taxa) do not share a most recent common ancestors.
Polyphyly The fact of being a group that does not include the most recent common ancestor of all of its members.
Polyploid Having more than one set of homologous chromosomes.
Polyramous Relating to or having an extension of the body (usually an appendage) with multiple branches.
Polythetic group A natural taxonomic group in which the terminal taxa are not known to share any universal unique character(s) but are nonetheless united by overall similarity (phenetics) or global parsimony (cladistics).
Polytomy The fact of many branches arising from a single node or an unresolved (partial or whole) cladogram.
Polyunsaturated fatty acids Fatty acids with two or more double bonds in the chain of carbon atoms. They occur in distinct families defined by the positions of the double bonds, of which the commonest are n-3 and n-6.
Poor fen A term for an acidic peat land similar to a bog but having a somewhat higher surface water pH (4.3–5.8), because it receives some ground water or surface water in addition to precipitation; typically dominated by sphagnum mosses or sedges.
Population A group of individuals of a particular species that live in a given region and that are more likely to mate with one another than with individuals from another such group elsewhere. A population is usually a subset of the entire species.
Population dynamics Changes in population size through time, and the processes that bring about these changes.
Population regulation The constraint of positive population growth. The study of population regulation deals with the factors that cause this constraint, such as predation or competition for food.
Population stability The tendency for populations to return to a previous size after a disturbance, such as increases due to immigration, or reductions due to predation, hunting, or disease. Stable populations may be locally stable (return after small disturbances) or globally stable (return after severe or catastrophic disturbances).
Population viability analysis (PVA) A method of assessing the probability of extinction for a given population within a specified time span.
Poricidal anthers In certain plants, anthers that function similarly to salt shakers; they must be vibrated at the right frequency (by buzz pollinators) to dispense pollen grains through the pores at the end of the anthers.
Postemergence herbicides Herbicides applied after the emergence of the specified weed or crop.
Posttranscriptional modification The process of cutting and splicing messenger RNA, in some cases to produce alternative transcripts and proteins with different structural or regulatory properties (e.g., sex determination in *Drosophila*).
Potential energy See ENERGY.
Potential (natural) vegetation The vegetation cover that would develop naturally in an area and become stable (not replaced by a subsequent stage) if all outside disturbances were eliminated.
Poverty A pronounced deprivation in well-being in which a person lacks opportunities, empowerment, and security. Typically measured by income level or by the ability to purchase food and other staples.
Precautionary principle The principle that when there is a threat of serious or irreversible environmental damage, lack of full scientific certainty about outcomes should not be used as a reason to postpone measures to avoid that damage.
Precession The drift of the timing of the point in the year when Earth is closest to the Sun (**perihelion**), which influences the distribution of insolation with season and latitude.
Predation An interaction between two species in which one species consumes the other.
Predator An animal that naturally preys on others to obtain its food.
Predator-prey relationship The ongoing ratio in a given habitat of the population size of a predator and that of its target prey.
Predatory Having to do with or exhibiting the behavior of predation.
Pre-emergence herbicides Herbicides applied prior to the emergence of the specified weed or crop.
Preservation 1. The school of conservation philosophy that emphasizes the protection of natural features and landscapes from human exploitation. 2. The fact of taking active measures to maintain ecosystem viability.
Preserve Another word for a RESERVE.
Presoldier In termites, a transitional morph that precedes the soldiers; an unsclerotized individual whose head shows signs of soldier differentiation.
Prevalence The proportion of hosts in a population that are infected or diseased.
Prevention Efforts to reduce the probability of an invasive species being introduced and subsequently becoming established in a new habitat.
Primary compounds See SECONDARY COMPOUNDS.
Primary forest A forest that appears to be undisturbed by human influence.
Primary hemiepiphyte A plant that begins its life cycle anchored in a tree crown and ultimately becomes rooted in the ground.
Primary host See DEFINITIVE HOST.
Primary mutualism The initial association between a symbiont and a host.
Primary producer An organism that is capable of producing biomass from inorganic compounds.
Primary production 1. The process in which organic matter is synthesized from carbon dioxide by photosynthesis. 2. The amount of energy produced by this process. Also, **primary productivity**.
Primary succession The development of an ecosystem on a substrate previously devoid of vegetation, such as a sandbar.
Prime Describing agricultural land that has the best combination of physical (e.g., moisture status, soil depth, or slope condition) and chemical (e.g., nutrient status and salinity) characteristics for producing food, forage, fiber, and oil seed crops.

Primitive Another term for ANCESTRAL.
Priority The principle in scientific nomenclature that the name with the first date of valid publication is generally the one to be used.
Priority areas Areas that need the most urgent management; e.g. action to avert a threat or to meet a conservation goal (such as to increase the likelihood of persistence of valued species).
Priority effect The effect of the existing presence of an individual or taxon on newly arriving individuals; can be negative or positive.
Prisoner's dilemma Uncertainty about others' behavior leading to choices that are individually rational but collectively irrational; based on a classic example in game theory in which two prisoners will collectively benefit if they act in a cooperative way, but they act selfishly in the interest of individual benefit. Can be used as a context for describing or analyzing animal behavior.
Private good A good whose consumption typically occurs as the result of a market transaction between buyer and seller; called *private* because one person's consuming it reduces the amount available to others, and the provider of the good can exclude some people; e.g., those who are not willing to pay for it. Examples of private goods are a pound of apples or a gallon of gasoline. Compare PUBLIC GOOD.
Procaryote Another spelling of PROKARYOTE.
Process-based model(ing) A model explicitly based on mathematical representations of processes or mechanisms, such as animal or seed dispersal. For example, population dynamics models describe the evolution over time of the population abundance by accounting for processes such as birth, death, and dispersal.
Producer See primary producer.
Producer surplus A measure of the welfare that producers gain from selling goods and services, usually measured as the difference between the actual market price and the minimum amount that they would be willing to accept for the good or service.
Production The amount of newly formed biomass of an individual, population, or trophic level, including the organic matter lost during the period of observation through processes such as respiration, excretion, injury, or predation.
Production-function An approach that models ecosystem services as the relationship between ecological and human inputs (e.g., the structure and functions of an ecological system, and human labor and capital) and outputs valued by humans.
Productive benefits Values that are bought and sold in markets, such as honey and timber, or that enhance goods and services sold in markets, such as real estate.
Prognathous Describing the position of the head when the mouth opening is directed forward.
Progressive Describing successions in which the dynamic changes are in the directions of increasing species diversity, structural complexity, greater biomass, and increased stability. *Retrogressive* successions are in the opposite directions.
Progressive Era The period in American political history, especially coinciding with the presidency of Theodore Roosevelt (1901–1909), in which the environmental conservation movement gained definition and popular support.
Prokaryote A single-celled organism that has its DNA arranged as a circular molecule not contained within a nucleus, and which reproduces by simple fission. Prokaryotes are members of the domains Archaea and Bacteria, as opposed to EUKARYOTES, all other organisms that do have a cell nucleus.
Propagule Any part of an organism capable of developing into a new individual, such as a seed, spore, egg, bud, and so on.
Propagule pressure A concept that encompasses variation in the quantity, quality, composition, and rate of supply of alien organisms resulting from the transport conditions and pathways between source and recipient regions.
Property right The legal and social construct under which owners of property cannot be deprived of it without the payment of compensation that is acceptable to them.
Prosimians A category of primates that are neither monkeys or apes, such as galagos, lorises, lemurs, and tarsiers.
Prostomium The most forward part of the body in annelid worms; may carry antennae and eyes and at least part of the brain.
Protandrous Existing first as a functional male, then as a female.
Protandry A breeding system in which individuals change sex from male to female.
Protein A three-dimensional macromolecule constructed of amino acids that is formed on the basis of an RNA sequence.
Protein probe array See DNA PROBE ARRAY.
Protherian One of the Protheria, egg-laying mammals that are mostly extinct but include the platypus and echidna.
Protist One of a diverse collection of mostly unicellular eukaryotes that are defined by their exclusion from other groups; i.e., they are not animals, plants, or fungi. Includes protozoa, simple algae and fungi, and slime molds and water molds.
Protogynous Existing first as a functional female, then as a male.
Protogyny A breeding system in which individuals change sex from female to male.
Protozoa A group of mostly unicellular eukaryotic organisms, usually classified as animals because they ingest food and are capable of movement. However, some forms regarded as protozoa, such as slime molds and euglenoid forms, have the properties of plants.
Protozoan (plural, **protozoans** or **protozoa**) One of the protozoa (see previous). Also, **protozoon**.
Provenance test An experiment, particularly in forestry, in which plants from different source locations are grown together in common conditions, often in multiple locations, as a basis for assessing genetically based differences in trait values.
Provisioning services Ecosystem services (see) that supply humans with needed provisions, such as water, food or fibers, biochemicals for use in medicine or industry, and energy sources (e.g., biomass fuels, hydropower). Also, **provision services**, **providing services**.
Proximate Directly related; immediate; e.g., the agent that causes a species to become extinct. Also, **proximal**.
Psammophilic Sand-loving; living or thriving in sandy soil.

Pseudergate A false worker; among termites, a temporarily nonreproductive individual serving the colony in nutrition, construction, or brood care, which results from a late, reversible deviation from the pathways to the imago and is characterized by reduced wing buds compared to nymphs of the same stage.
Pseudocoelom A body cavity (coelom) not lined with a mesodermal epithelium.
Pseudoextinction The disappearance of a species from the fossil record due not to the death of all its members but rather to an evolutionary change that results in it being reclassified as a new species.
Psychrophile An organism that grows better at low temperature or that requires low temperature for growth. Such a condition is **psychrophily**.
Public good A good whose consumption is both *nonrival* and *nonexcludable*. That is, one person's consuming it does not preclude another (a rival) from doing so, and the provider of the good cannot exclude those who have not paid for it. Examples of public goods are clean air, a fireworks display, or a lighthouse. Compare PRIVATE GOOD.
Pull of the recent A term reflecting the fact that recently formed rock is more accessible and offers better preserved fossils; this may produce a bias toward the conclusion that diversity has increased toward the present time.
Puna An ecosystem of the high Andean mountains, found above the tree line from Bolivia to southern Peru. It has four distinct ecological regions: wet, dry, thorny, and desert. The dominant vegetation types vary from grassland/shrublands to desert.
Punctuated equilibrium The morphological stasis of fossil species over long periods of time, punctuated by seemingly abrupt speciation and morphological change.
Purebred An animal that is a member of a recognized livestock breed, as determined by pedigree records, geographical location, or knowledge of the breeding structure of the herd or flock.
Pure culture An organism growing in the absence of all other organisms.
PVA Population viability analysis.
Pycnocline The water layer in which density changes most rapidly with depth and separates the surface mixed layer from the deeper waters.
Quasispecies Hierarchically ordered populations of mutants resulting from erroneous copying of a genotypic ancestor. Whole mutant distributions behave like single species and are subjected to natural selection.
Quaternary The past 2 million years (approximately) of Earth's history, including the Pleistocene and Holocene (or Recent) epochs, particularly characterized by the extreme fluctuations in global temperature patterns that produced the ice ages. See also LATE QUATERNARY.
Queens and kings A term for females and males that actively reproduce in a colony.
Quiescence A state of dormancy in which inhibition of development depends directly on environmental factors.
R0 The basic reproductive ratio of a parasite or pathogen. For a microparasite, this describes the number of new infections generated by a single infected host entering an entirely susceptible population. For a macroparasite, R0 is the number of adult offspring produced by a single adult parasite over its lifespan.
Radiation All the species descended from a single common ancestor; tends to be a more diverse group in comparison with others of a similar age.
Radiative forcing A measure used to express and compare the potential of contemporary climate system changes (vs. preindustrial ones) to perturb the Earth's energy balance; reported in watts per square meter (W/m^2). A positive radiative forcing tends to warm the Earth's surface, and a negative one tends to cool the surface.
Radiocarbon dating The dating of organic matter in geological samples using as the standard the radioactive decay of Carbon-14, which has a half-life of about 5, 750 years. When a plant or animal dies it has approximately the same level of Carbon-14 as the atmosphere, but this decreases from that point onward. By dating tree rings of known age, and other methods, radiocarbon determinations can be calibrated.
Radula In mollusks, a ribbon-like structure bearing transverse rows of small "teeth," typically used to collect food and move it into the mouth.
Rainshadow A less rainy sector on the leeward side of mountains and protected valleys, caused by descending warm air masses.
Rami See CAUDAL RAMI.
Range 1. The extent of the area in which a given organism or species is found. 2. See **rangeland**.
Range core See CORE RANGE.
Range expansion The process in which a species spreads into new areas (usually new regions, rather than local-scale movements) due to natural dispersal, though the expansion may be assisted by human-mediated changes to the environment. The concept can be applied to both native and alien species.
Rangeland Land on which the potential native vegetation is predominately grasses, grass-like plants, forbs, or shrubs. Rangelands include prairies, marshes, tundra, wet meadows, savannas, shrubland steppe, chaparral, desert grasslands, and woodlands.
Range periphery The marginal parts of the distribution of a species.
Range state A country in which an animal is found.
Rank-abundance curve A plot of the number of individuals in each species ordered by their rank, starting with the most abundant species and ending with the most rare.
Rapoport effect A pattern in which the size of a species' geographic range increases toward higher latitudes. [Named for the Argentinean ecologist Eduardo Rapoport, who observed this pattern.] Also known as **Rapaport's rule**.
Rare A classification for species with small populations globally that are not presently listed as endangered or vulnerable, but are at risk because of their limited population size.
Rarefaction A statistical interpolation method of rarefying or thinning a reference sample by drawing random subsets of individuals (or samples), in order to standardize the comparison of biological diversity on the basis of a common number of individuals or samples.
rDNA See RECOMBINANT DNA.

Reaction center A bacteriochlorophyll–protein complex that performs the primary photochemical reactions of photosynthesis.
Reaction norm The relationship between the phenotypic expression of a single genotype and the environmental conditions under which the phenotype is shaped.
Reactive nitrogen All forms of nitrogen except atmospheric dinitrogen gas, including all radiatively, photochemically, and biologically active inorganic forms (e.g., NH_3, NH_4^+, NO_x, HNO_3, N_2O) and organic molecules (e.g., proteins, urea, etc.).
Realm See BIOGEOGRAPHIC REALM.
Rear edge A stable margin of a species' range where population size is declining.
Recalcitrant Describing seeds that have high moisture content and lose viability if moisture drops below a critical amount limiting their storage for long periods.
Recipient control A situation in which consumers substantially depress populations of their resources.
Reciprocal selection Evolutionary change as a result of species acting as selective agents on each other through interspecific interactions.
Reclamation 1. A revegetation or land management goal that includes a lower diversity of species and may include substitutions by introduced species. 2. The conversion of an area of the ocean, a lake, a riverbed, or a wetland to dry land. 3. The restoration of depleted or desert land to productive agricultural land. 4. The cleansing of wastewater for return to the natural environment.
Recolonization The reappearance of a species in an area where it has earlier been present, then disappeared.
Recombinant DNA (rDNA) A DNA sequence obtained by artificially combining two or more different DNA strands, thus creating a sequence that would not be found in nature. Recombinant DNA is widely used in biotechnology, biomedicine, and research; e.g., comparative phylogenetic studies.
Reconstructed evolutionary tree A phylogeny linking contemporary species, and thus containing no information about lineages that have gone extinct.
Recruitment The arrival of new juvenile animals or plants into a habitat or an older stage of the population; e.g., the entry of juvenile fish into the adult stock.
Recruits A term for young fish that are first caught by a fishery.
Recycling 1. The process of reusing industrial materials (e.g., aluminum, glass, plastic, paper) after the initial use, to preserve useful materials and reduce the need for manufacturing new materials (as well as for other benefits). 2. The transpiration and evaporation of water from the land surface, followed by reprecipitation elsewhere within the continent.
REDD Reduced emissions from deforestation and forest degradation; a form of payment for ecosystem services in which the carbon storage value of forests threatened by degradation or clearance is financially recognized through payments to forest owners (usually, but not exclusively, nation-states) to conserve the forest.
Redfield ratio The ratio of carbon, nitrogen, phosphorus, and oxygen for normal ocean plankton and deep-ocean nitrate and phosphate pools, on the basis of time-averaging for a large-area. Also, **Redfield stoichiometry**. [Described by the U.S. oceanographer Alfred C. Redfield.]
Red list See IUCN RED LIST.
Red tide The popular name for a harmful algal bloom (HAB) having a reddish or brownish coloration. See ALGAL BLOOM.
Reference area An undisturbed or natural area chosen to compare with a restored site to determine the success of restoration.
Reflective beach A narrow, steep beach; so called because it reflects a major part of the incoming waves.
Reforestation The re-establishment of trees and understory plants at a site previously occupied by forest cover. This can occur by natural means or by some form of human intervention, including planting seedlings or sowing seeds.
Refugia Arctic land areas that were not covered by ice sheets or glaciers during the last glaciation. Consequently, some biota could survive there and recolonize adjacent areas when the ice retreated. Therefore, these areas are associated with high biodiversity and endemism. Refugia usually occurred in coastal areas (now continental shelves) and ice-free mountain tops or "nunataks."
Regenerated production Primary production in the ocean derived from recycling of nutrients within the euphotic zone such as by uptake of ammonia (NH_4^+) or dissolved organic nitrogen. Compare NEW PRODUCTION.
Regeneration 1. The ability of organisms to regrow lost or destroyed tissue or body parts. 2. See FOREST REGENERATION.
Regime The specific, relatively stable structural and functional state of a given ecosystem.
Regime shift A large, persistent, often abrupt change in the structure and function of an ecosystem, associated with a change in dominant feedback processes. Regime shifts are abrupt and often difficult to reverse.
Region A large geographic area that contains more than one landscape.
Regional pool Species occurring within a defined geographical area or in a collection of samples from within such an area.
Regulating services The ecosystem services (see) obtained from the regulation of environmental processes, including flood protection, climate regulation, human disease regulation, water purification, air quality maintenance, pollination, and pest control.
Rehabilitation The process of re-establishing the productivity and some, but not necessarily all, of the plant and animal species thought to be originally present at a site. For ecological or economic reasons, the new ecosystem might also include species not originally present at the site. The protective function and many of the ecological services of the original system may be re-established.
Reintroduction The placement of individual organisms by humans into a habitat for the purpose of establishing a population where a previous population has gone locally extinct.
Relative abundance distribution A frequency distribution depicting the number of species in a community as a function of the number of individuals comprising each species.
Relay intercropping See INTERCROPPING.

Relict 1. Surviving; being a survivor. 2. A surviving species of an otherwise extinct group of organisms. **3**. A formerly numerous and widespread species that now persists only in small numbers in a limited area.

Relictualization The survival of species on islands or other relatively small areas, after those on larger mainland areas have suffered extinction.

Remediation The removal of toxicants from a contaminated environment, using chemical, physical or biological means.

Remote detection The assessment of a particular variable or parameter from afar, without a local human presence; e.g., a substance that could be dangerous to investigate at close range.

Remote sensing The technique of obtaining information about an object, area, or phenomenon through the analysis of data acquired by a device that is not in contact with the object, area, or phenomenon under investigation (e.g., by means of a satellite image).

Renewable Describing a resource that can be grown or produced at a level which over time will sustain its consumption rate, assuming sustainable use in the present; for example, wood, agricultural plants, fish stocks. Contrasted with NON-RENEWABLE.

Renewable energy Those forms of energy (**renewables**) whose transformation does not consume the ultimate source of the energy, harnessing instead sources such as solar radiation, wind, the motion of water, and heat from subsurface water and geologic formations. The major forms of renewable energy are solar, wind, geothermal, hydropower, and biomass. Compare NON-RENEWABLE ENERGY.

Renewable fuel A fuel obtained from a renewable source, such as ethanol from corn.

Renewable Fuel Standard (RFS) A U.S. federal government mandate requiring certain quantities of four categories of biofuels to be used (e.g., by the blending of biofuels into gasoline), with the total reaching 136 billion liters (36 billion gallons) of ethanol equivalent by 2022.

Renosterfeld Evergreen, needle-leaved shrubland on richer soils of the Cape Floristic Region of South Africa; dominated by the resinous shrub *Elytropappus rhinocerotis* (Asteraceae), whose name literally means "rhinoceros bush."

Rent See ECONOMIC RENT.

Repetitive DNA Regions of DNA that include the same DNA sequence repeated several hundred or thousand times; regions with repeated segments that involve only 2–5 base pairs of DNA are called **microsatellites**.

Representation The occurrence of species (or other attributes) within a set of selected areas.

Reproductive isolation The existence of intrinsic barriers (e.g., large rivers, mountain ranges) to the production of offspring.

Reproductive success The number of an organism's offspring surviving to sexual maturity, relative to the number produced by others in the same population.

Reptile A member of a class of vertebrates (the Reptilia), including turtles and tortoises (order Testudinata), lizards, snakes, and worm-lizards (order Squamata), the tuatara (order Rhynchocephalia), and crocodiles and alligators (order Crocodylia). Reptiles typically lay eggs with a leathery, impermeable shell and have a dry, horny skin with scales, plates, or scutes.

Rescue effect A reduction in the likelihood of local extinction in a habitat patch by the presence of emigrants from other habitat patches.

Reserve An area in which the primary management objective is to fully protect native species and ecosystems from direct human modification.

Reserve selection algorithm A mathematical technique used to maximize efficiency in the selection of protected areas for conservation. The efficiency criteria vary with circumstances but may, for example, be the minimum number of reserves with every species represented, or minimum cost.

Reservoir competence The degree to which a host is capable of supporting pathogen proliferation and transmission to other hosts or to vectors.

Reservoir host A host organism that can carry and transmit a parasite or pathogen to other host species, while suffering little or no negative effects itself.

Residence time The length of time that a given unit of water remains in a given place and thus reflects the exchange rate of water at that place. It can be calculated in various ways; e.g., by dividing the volume of the area of interest (e.g., a floodplain site) by the flow rate.

Residual impact The remaining adverse impact on biodiversity after appropriate avoidance, minimization, and restoration actions have been taken according to the mitigation hierarchy.

Resilience 1. The ability of an ecosystem to recover to conditions similar to those that existed prior to the imposition of a disturbance. 2. The rate at which such a recovery occurs.

Resistance 1. The degree to which an ecosystem is able to remain unchanged when subjected to a disturbance; e.g., climate change. 2. The ability of an individual to minimize the effects of a disease or other harmful agent. **3**. The fact of a harmful pest having reduced susceptibility to a given pesticide.

Resolution 1. The magnitude of the biological response to a toxic chemical. 2. The unit size of the information presented in an ecological model.

Resource 1. Anything that is used or consumed by an organism for growth, maintenance, reproduction, or survival, including food, space, and shelter. 2. Any substance, material, process, or feature that has value for human use, either natural or man-made. See also NATURAL RESOURCE.

Resource catchment The locality from which the resources consumed by a group of people are derived.

Resource conservation See CONSERVATION.

Resource facilitation The fact of the activity of one species promoting the availability of resources for another species; e.g., a plant that provides shelter (or greater access to sunlight) for another.

Resource partitioning An ecological arrangement in which two or more species use different, non-overlapping resources in a given habitat, such as birds foraging for insects in different locations within a tree or canopy.

Response curve The relationship between a species probability of occurrence or its density (number of individuals per unit area) and the values of a given environmental variable.

Resprouting In woody plants that are damaged but not killed by fires, the growing of new leaves, either from the base or from epicormic shoots (new shoots originating beneath the bark).
Restoration A process of assisting in the recovery of damaged, degraded, or destroyed ecosystems, by the manipulation of organisms and ecological processes to create self-organizing systems that resemble predisturbance structure and functioning and promote biodiversity. The study of such a process is **restoration ecology**.
Reticulate evolution A pattern of speciation in which new species arise from interspecific hybridization between two species, coupled with establishment of reproductive isolation.
Retinal The rhodopsin chromophore, responsible for the color of rhodopsin pigments. Also called **retinaldehyde** or **vitamin A aldehyde**.
Retrogressive See PROGRESSIVE.
Revegetation The process of replanting grasses, bushes, and other types of vegetation on cleared and bare soils.
RFS Renewable Fuel Standard.
Rhizodeposition The mixture of sloughed cells, mucilages, and low molecular-weight sugars, amino acids, and other compounds leaked from root cells, which are deposited in the soil adjacent to the surface of fine roots.
Rhizoplane The soil directly in contact with the plant root surface.
Rhizosphere The volume of soil adjacent to, and strongly influenced by a plant root; usually considered to extend about 2 mm from the root surface.
Ribosomal RNA (rRNA) A segment of ribonucleic acid (RNA) that serves as a structural element of a ribosome. Ribosomes are macromolecules that translate messenger RNA into protein. They are universally distributed molecule among cellular life forms and are widely used to infer evolutionary relationships.
Ribotyping The fingerprinting of genomic DNA restriction fragments that contain all or part of the ribosomal RNA gene, in order to identify and distinguish among strains or species (which are thus defined as **ribotypes**).
Rich fen An alkaline peat land that receives significant inputs from ground water or surface water, typically having surface water pHs 4–6.0, higher alkalinity, and distinctly higher concentrations of base cations than bogs and poor fens. Such terrain is dominated by brown mosses (true mosses, largely of the Amblystegiaceae) and small sedges.
Richness See SPECIES RICHNESS.
Riparian having to do with rivers; located in or on a river.
Riparian forest A forest that grows adjacent to rivers and within floodplains, generally composed of trees tolerant of periodic flooding and riparian trees that require flooding to promote their regeneration.
Riparian zone The interface between rivers or streams and terrestrial uplands. These zones are three-dimensional areas of direct interaction between the terrestrial and aquatic ecosystems, and they often contain unique species and high levels of biological diversity.
Risk A situation in which outcomes are stochastic (not deterministic) but each alternative has a known probability of occurrence. Risk may be idiosyncratic (specific to an individual) or systemic (shared).
River continuum A series of conceptual, unifying models to explain and predict the structure and function of river ecosystems.
RNA Ribonucleic acid, composed of nucleotides as is DNA, but in RNA the base uracil (U) replaces the base thymine (T); RNA molecules form important structural and regulatory parts of cells.
Root length density (RLD) Root length per unit of soil volume (m/m^3 or cm/cm^3).
Root parasite A parasite that forms haustoria (penetrating parts) on the roots of the host plant.
Root weight density (RWD) Root fresh or dry weight in unit soil volume (g/cm^3).
Rostrum 1. A beak; any of various beaklike structures in different organisms. 2. Specifically, elongated mouth parts in certain insects, adapted for piercing the organisms on which they feed.
Rotation See CROP ROTATION.
rRNA See RIBOSOMAL RNA.
Rubisco (RuBisCO; RuBP) Ribulose-1,5-bisphosphate carboxylase oxygenase, the central enzyme of photosynthesis.
Rubisco capacity The maximum rate of carboxylation (incorporation of carbon dioxide into carbohydrates), determined principally by the amount of Rubisco (see previous) and other proteins needed for photosynthesis.
Rumen The first, and usually largest, chamber of the four-chambered stomach found in ruminant ungulates; the place where cellulose digestion occurs.
Ruminant 1. A grazing mammal with a complex four-chambered stomach (including a rumen). Common ruminants include cattle, sheep, goats, deer, antelopes, and giraffes. 2. Having to do with or being such an organism.
Runoff Water that is left over after evapotranspiration; the source of fresh water in streams and rivers.
Russell cycle A major change in the biota of the western English Channel from 1925 to 1972, in which first there was a change from one fairly stable configuration of organisms to another very different one, followed by a return to the first. [Named for British marine biologist Frederick Stratten Russell.]
SAD Species abundance distribution.
Sahul A collective term for New Guinea, Australia, and their islands.
Saltation 1. An abrupt, large-scale evolutionary change. Contrasted with GRADUALISM. 2. The movement of sand or other particles "jumping" across the surface due to wind or water action.
Salt wedge Water from the ocean, with higher salt content, that moves into an estuary along the bottom of the water column, beneath less dense fresh water that has moved into the same area from a river. The salt content makes the ocean water heavier than the fresh (riverine) water, so that under calm conditions, the estuarine water becomes density-stratified.
Sampling effect The hypothesis that diversity might influence an ecosystem process because of the greater chance that a given species trait would be present at higher diversity, and the effect of its presence on ecosystem functioning.
Sandwich hybridization A method for detecting and quantifying specific sequences of nucleic acid. A **sandwich**

hybridization assay employs a capture probe to immobilize a target molecule onto a solid support and a signal probe to reveal its presence.
Saprotroph A detritus eater; an organism that feeds on dead organic matter; e.g., a fungus or bacterium. Also, **saprovore**. Such an organism is **saprotrophic**.
SAR Species-area relationship.
Satellite virus A virus that does not encode all of the structural or enzymatic components required to replicate itself in a given host cell, but which can replicate through coinfection with a helper virus which provides the missing functions.
Saturated fatty acid A fatty acid with the maximum complement of hydrogen atoms and no double bonds between carbon atoms.
Saturation The upper limit to species richness within a community, set by species interactions, and independent of the pool of colonists for which that community is accessible.
Saurischian One of the Saurischia, the so-called reptile-hipped dinosaurs, including sauropods (see next) and theropods.
Sauropod One of the Sauropoda, quadripedal herbivorous dinosaurs that are the largest animals ever to have lived on land, including such well-known genera as *Diplodocus*, *Brachiosaurus*, and *Apatosaurus* (*Brontosaurus*).
Savanna A mixed tree and grass system, with trees ranging from sparse to medium dense, with an understory of grasses. Savannas are open, well lit systems. Rainfall usually occurs in the warmer, summer months with a dry period of 2–8 months. Fires are typical across savannas during drier months, and occur at intervals from 1 to 50 years. Also spelled **savannah**.
SC Synaptonemal complex.
Scala naturae "Nature's ladder;" the medieval concept of life as being arranged in a hierarchical chain or ladder, with God and the angels at the top and living things on Earth below, placed according to their perceived complexity. Thus a typical progression would be inanimate materials (minerals, soil), plants, insects, fish, amphibians, reptiles, birds, mammals, humans. An influential belief in the early days of modern biology but eventually abandoned, though reminders of it still exist, as in the idea that mammals, birds, and reptiles constitute the "higher" vertebrates. Also known as the **Great Chain of Being**.
Scale The distance or time over which a significant change in some quantity of interest can be measured.
Scale dependence A condition in which either the form or the parameters of a relationship between two variables (e.g., species richness and latitude) is contingent on spatial or temporal attributes.
Scale of effect The spatial extent over which the habitat and the matrix characteristics in the surrounding landscape influence individual, population, or community processes in a focal area.
Scansorial 1. Adapted for or capable of climbing. 2. Using both the forest floor and canopy for movement and seeking resources.
Scent glands Glands through which many types of organisms secrete various compounds for purposes such as defense, marking of territory, attraction of mates, and attraction of both sexes.
Scleractinia The taxonomic order of cnidarians, marine invertebrates including the reef-building corals.
Sclerophyll A plant with tough, leathery, evergreen leaves, usually associated with drought resistance.
Sclerophyllous Describing leaves with a leathery texture due to the presence of **sclerenchyma** cells with large amounts of lignin and cellulose in their tissues.
Scutellum "Little shield;" the dorsal portion of the insect mesothorax, in most heteropterans it is triangular or shield-shaped.
Seagrasses A collective term for grasslike flowering plants that are able to grow submerged in marine and estaurine waters, to which they are restricted.
Seasonal dimorphism A trait in which plant species change the morphology of leaves throughout the year to adapt themselves better to prevailing temperature and water stress.
Secchi depth Measurement of the transparency of water by determining the depth at which a white **Secchi disk** (diameter 20 cm) lowered from the surface disappears out of the sight of the observer. [Developed by the Italian scientist Father Angelo Secchi.]
Secondary compounds Chemical compounds that serve as defenses in plants; contrasted with **primary compounds** that are involved with processes of primary metabolism, such as photosynthesis and cellular respiration.
Secondary extinction The extinction of a species resulting from the extinction of another species on which it relies.
Secondary forest An area of previously forested land that was subsequently degraded or deforested through human or natural action but which now supports regenerating or mature natural forest.
Secondary hemiepiphyte A plant that begins its life cycle as a terrestrial seedling, ascends a tree, and can later lose root connections with the ground, including both lianas (see) and vines.
Secondary host See INTERMEDIATE HOST.
Secondary metabolite An unusual compound that does not play a role in primary metabolism (e.g., production and storage of energy). Such metabolites were initially thought to be waste products but are now known to have adaptive or defensive value.
Secondary mutualism The incorporation of a primary mutualism into a secondary host; the primary host either becomes the symbiont or is lost.
Secondary production The production of new living material through tissue produced by heterotrophic organisms, which consume living or dead material from other organisms. Compare PRIMARY PRODUCTION.
Secondary succession The re-establishment of an ecosystem on existing substrate (soil), following a disturbance that removes existing vegetation.
Seed bank An accumulation of dormant plant seeds that persist in dormancy for longer than a single growing season.
Seeding 1. The process of planting or sowing seeds. 2. Describing plants whose seeds germinate abundantly after fires, thus quickly re-establishing a population from seeds.

Segregation The allocation of genetic variants (alleles) to different gametes during sexual reproduction.
Selection The differential survival or reproductive success of individuals, associated with differences in phenotype or genotype.
Selection regime A situation in which a particular set of evolved traits is favored; thus a newly established population will evolve in a different direction from the ancestral population.
Selective constraint See FUNCTIONAL CONSTRAINT.
Selective logging A less intense form of timber extraction involving removal of select trees, often based on species, size, or age class. The forest canopy is typically maintained under this process.
Selectivity A phenomenon in which some plants are killed with doses of herbicides that have little or no effect on other plants.
Self-incompatibility A genetically based system that prevents fertilization of an egg by pollen that shares one or more alleles at a self-incompatibility locus; a mechanism to prevent self-fertilization in plants.
Self-organization 1. A process in which pattern at the coarse scale of a system emerges solely from numerous interactions among the lower-level components of the system. 2. Specifically, the spontaneous formation of complex structural aggregates from biological macromolecules such as proteins, nucleic acids, or lipids. The assembly pathways are usually determined by physicochemical properties of the constituent molecules.
Self-pollination The pollination of a flower by pollen from the same flower, or from another flower on the same plant.
Semaphoront An assemblage of individual organisms at a particular point in time in their developmental (ontogenetic) history.
Semiparasite Another term for a HEMIPARASITE.
Semelparity The fact of breeding only once and then dying, or the process of doing this; sometimes called "big bang" reproduction because it is both conclusive and large-scale. Compare ITEROPARITY.
Semelparous Describing an organism that produces offspring (flowers and fruits in plants) only once in its lifetime before dying.
Seminatural Describing vegetation that owes its character to human activity, but in which the plants are wild, not sown nor planted; e.g., coppice woods; most heathland; some savannas. Seminatural vegetation can provide suitable habitat for a large number of native species.
Semishrub A plant whose new growth is herbaceous but whose older base parts are woody. Also called a SUBSHRUB.
Semi-steppe batha Semishrub communities developing on most soil types at the boundary of the Mediterranean zone of the Near East.
Sensu Latin for "in the sense of;" used to describe how precisely or generally a term is defined. A *sensu stricto* usage employs the narrower sense of the term; a *sensu lato* usage is more inclusive. An example would be the term *symbiosis* which can be defined strictly as a mutually beneficial relationship between organisms. or more broadly as any long-term association, regardless of effect.
Sere 1. One of a series of stages in an ecological succession sequence, or the entire set of stages. 2. Describing withered, very dry vegetation, or an area with such vegetation.
Serotiny The fact of seeds being stored on a plant with dispersal triggered by fire or another such event.
Setae (singular **seta**) Bristle- or hair-like structures, such as the extensions of the cuticle that are characteristic of arthropods and related phyla.
Settlement Land used for human habitation, including cities, towns, villages, rural communities, roads, and so on.
Sexual selection Selection that acts directly on mating success through direct competition between members of one sex for mates, through choices made between the two sexes, or through a combination of both.
Shadow price A measure of the social opportunity cost of resource use; the net increase in societal well-being that would be enjoyed if a unit more of the resource were made available, other factors being equal. Since shadow prices reflect the social scarcities of capital assets, it is only in exceptional circumstances that they equate to market prices.
Shannon entropy An index that quantifies the uncertainty regarding which type (such as species) is picked when one entity (such as an individual) is drawn at random from the data set of interest. Often used as a diversity index. [Described by U.S. mathematician Claude Shannon.]
Shelf See CONTINENTAL SHELF.
Shifting cultivation A cyclic agricultural system widely used throughout the tropics; it involves cutting and burning of small patches of forest, followed by several years of crop cultivation, then a fallow period during which the forest regenerates and can be cleared again. Also, **shifting agriculture**.
Shoot growth Biomass production (per hectare) of foliage shoots produced annually in the overstory of a plant community.
Shotgun DNA A technique that isolates DNA (deoxyribonucleic acid) fragments from soil or water samples and compares them to known DNA libraries to determine the presence of novel species.
Sibling species A pair of closely related, morphologically similar species (usually sister species).
Siderophores Chemicals secreted by roots (primarily non-protein-forming amino acids), which complex with insoluble metal ions, bringing them into solution and permitting their transport to and uptake into the root.
Silvics The scientific study of forest trees, including their life history, growth, reproduction, and response to environmental change.
Silviculture The branch of forestry concerned with the theory and practice of controlling forest establishment, composition, and growth.
Simpson (diversity) index An index of diversity based on species abundance data. If p_i is the frequency of species i in a community of n different species, then Simpson diversity $= (1 - \Sigma_i^n = p_i^2)$ and is equal to the probability that two randomly chosen individuals from a given community are of the same species.
Simulation buffer The area surrounding a context landscape that allows for the spread of spatial processes into this landscape.

Simulation landscape The area being simulated to produce an HRV (historic range of variability; see) time series that usually includes both the context landscape and the simulation buffer.

Sink 1. A physical reservoir of a compound that can take up additional quantities of this compound from the air and thus reduce its atmospheric concentration. 2. Specifically, a component of the carbon cycle that is a net accumulator of carbon annually, such as the ocean or the forests.

Sink population A deme (localized breeding group) in which death rates exceed birth rates. Sink populations will go extinct without an input of immigrants.

Sirenian One of the Sirenia, the order of marine mammals that includes the manatees, dugongs, and seacows.

Sister groups Two terminal taxa or monophyletic groups that share a common ancestor that has not given rise to any other taxon under consideration.

Sister species (taxa) A pair of species (taxa) that have arisen from a single speciation event; each is the other's closest relative.

Site history The collection of past events involving natural disturbance or land use conversion at a given site.

Smolt A downstream migrating salmon that has begun the physiological transition to seawater.

SMRS Specific mate recognition system.

SNP Single nucleotide polymorphism; population variation at one nucleotide position.

Social cooperation A mutually beneficial association, temporary or permanent, among members of the same species.

Social costs The total costs to society of an action. These may exceed (or in some cases be less than) the private costs, which are the costs of that action to the individual or institution executing it.

Social differentiation The specialization of functions in a human society, as societies increase in size and complexity over time.

Social discount rate The rate at which society is willing to substitute future consumption for present consumption.

Social ecology The ecological study of various social species such as ants, bees, wolves, dolphins, and orangutans (or humans).

Social equity The fair, just, and equitable distribution of the stocks or flows of capital assets that contribute to human well-being.

Soil aggregate A crumb-sized unit of soil, composed of aggregated soil minerals, microbes, and soil microfauna, which are cemented together by a combination of biological materials such as polysaccharide secretions, fungal hyphae, and precipitated carbonates or silicates and other chemical substances. Aggregates are classified by their size and stability in water (disintegrating versus retaining their structure and integrity).

Soil horizon One of the distinct horizontal layers making up the soil. They range from the rich, organic upper layers of humus and topsoil known as the **O Horizon** and **A Horizon**, through the **E Horizon** (an intermediate leaching layer), to the underlying rocky layers of subsoil (**B Horizon**), regolith (**C Horizon**), and bedrock (**R Horizon**).

Soil organic matter (SOM) Organic substances, including a wide variety of carbohydrates, proteins, lipids, waxes, phenolic, and humic compounds, that accumulate in soil as a result of both plant and microbial growth. These include materials of low molecular weight that are rapidly decomposed to carbon dioxide; larger compounds that may be slowly decomposed over years to decades; and large, complex, aromatic substances, which may be stable within the soil for millennia.

Soil salinization index The molar ratio of soda and potash over alumina, determined by whole-rock chemical analysis, and used as a proxy for paleotemperature.

Soil structure A spatial arrangement of soil particles.

Soil texture The relative abundance of sand, silt, and clay particles in the soil. Particle size distribution determines the distribution of pore sizes, which in turn strongly affects the behavior of water in the soil.

Solar-heated Describing water whose temperature significantly exceeds the regional temperatures of lakes and streams. Many of the thermally tolerant and thermal-opportunist groups of organisms are thought to have evolved in shallow solar-heated ponds and water margins.

Sole cropping The agricultural practice of having one crop variety grown alone in pure stand at normal density.

SOM Soil organic matter.

Source population A deme (localized breeding group) in which birth rates exceed death rates. Sources produce an excess of individuals who will emigrate from that deme.

Source-sink dynamics Dynamics between populations that are net exporters of individuals (source populations) and populations that are net importers (sink populations).

Southern Ocean The circumpolar ocean in the Southern Hemisphere between the Subtropical Front and the continent of Antarctica.

Spatial Having to do with physical space; measured by or in the context of space.

Spatial autocorrelation The fact that observations are not independent identically distributed, but are correlated over some distance in space. **Positive autocorrelation** indicates that nearby values are similar; **negative autocorrelation** indicates that nearby values are dissimilar.

Spatial heterogeneity In community sampling, variation in species capture probabilities across space; this may be due to habitat variation, intraspecific clumping, interspecific association, or other factors.

Spatial subsidy Input from other habitats of organic carbon, nutrients, and prey or the movement of consumers. These resources can significantly influence the energy, carbon, and nutrient budget of recipient habitats.

Spawner A mature individual of a stock responsible for reproduction.

Specialist brood parasite A species that parasitizes only one or a few host species.

Specialization An evolutionary adaptation to a particular mode of life or habitat.

Speciation Development of species; the evolutionary process by which new species arise in a biological system.

Species A fundamental category for describing organisms, defined in several ways but typically on the basis of reproduction; i.e., members of a species can interbreed freely

with one another to produce fertile offspring, but cannot do this with members of other species. In taxonomic classification, a species is a subdivision of a genus.
Species abundance distribution (SAD) The number of species in a community as a function of abundance.
Species accumulation curve A representation of the total number of species observed in an assemblage, plotted against some measure of cumulative sampling units. Similarly, **species-area curve** or **model**.
Species-area relationship (SAR) The relationship between the size of a given habitat or area sampled across habitats, and the number of species (typically of a specific taxonomic group) found in that area.
Species Distribution Model A model used to describe and understand the geographic distribution of species, usually through interpolation and/or extrapolation of empirically derived correlations between environmental factors and the presence or absence of the species.
Species diversity A measure of diversity that incorporates both the number of species in an assemblage (species richness) and the way their abundances (i.e., number, biomass, and cover) are distributed (species evenness).
Species evenness The degree to which all species have the same proportional abundance.
Species flock(s) An aggregate of closely related species that share a common ancestor and are endemic to a geographically circumscribed area.
Species lifespan The time between the first appearance of a species in the fossil record and its final disappearance. This time span is typically in the range of millions of years.
Species niche See NICHE.
Species optimum The value of a given environmental variable at which a species reaches its maximum probability of occurrence or abundance.
Species packing The study of how species on the same trophic level coexist in a limited region or context.
Species pool The set of species that are able to colonize a habitat of interest.
Species range See RANGE.
Species response curve See RESPONSE CURVE.
Species richness The total number of species present in a habitat or ecosystem, with each species given an equal weighting; this is the simplest measure of biodiversity for that area.
Species turnover See TURNOVER.
Specific mate recognition system (SMRS) One of the fertilization and mate recognition systems in the recognition concept of species; i.e., the factors leading to premating compatibility within a species.
Specificity The ability to relate a chemical effect to a distinct biological function or organism.
Speciose Of high diversity; having many species. Contrasted with DEPAUPERATE.
Spermatophore In various species (e.g., insects), a chitinous container produced by the male to hold sperm. It may be attached to the substrate for the female to locate, or passed to the female from the male during mating.
Spicule In certain nematodes, a bladelike, sclerotized male copulatory organ, usually paired, located immediately dorsal to the cloaca.
Spillover The transmission of a pathogen from reservoir hosts to other species that generally do not sustain the pathogen.
Spinneret One of usually three, rarely four pairs of modified terminal abdominal appendages in spiders, bearing one to hundreds of hollow spigots from which silk is drawn (spun).
Spore A walled, typically unicellular reproductive structure found in many organisms, adapted for dormant survival in unfavorable environmental conditions, sometimes over vast time periods. Capable of developing into a new individual without fusion with another sexual body if conditions are favorable.
Sporophyte In an organism with an alternation of generations, the diploid, spore-producing phase.
Sprawl inequality The concept that the majority of habitat loss from urban expansion is due to a minority of new housing unit creation, typically lower density sections at the edges of the urban area. Similarly, a minority of households live on land parcels that cover the majority of the urban area.
Spreading rate The rate at which tectonic plates move apart from each other.
SSU rDNA The gene in DNA that codes for the ribosomal RNA in the small subunit (SSU) of the ribosome. This is 16 S rRNA in prokaryotes and 18 S rRNA in eukaryotes.
Stabilizing mechanism A biotic or abiotic force that introduces a tendency for species to increase when rare, giving rise to niches and possible stable coexistence of multiple species in a community.
Stabilizing selection Selection that favors intermediate phenotypes (hybrids between incipient species). Compare DISRUPTIVE SELECTION.
Stage The lowest-ranking unit in the hierarchy of terms for stratigraphic intervals that can be recognized on a global scale.
Stasis 1. A state of stability or equilibrium; lack of change. 2. Specifically, the persistence of organisms that greatly resemble their fossil forebears, through long geological periods of time. Also, **stasigenesis**.
Stem A term for the branch on a cladogram between node and term.
Stem parasite A parasitic plant that forms haustoria on the stems of a host.
Stenotopic Occupying a highly specialized habitat, or tolerating a narrow range of environmental conditions.
Stewardship 1. The management of a thing for someone or something else. 2. Specifically, the ethical concept that humans have the responsibility to serve as a **steward**, or watchful caretaker, with respect to the natural environment, acting to protect natural resources and preserve biological diversity.
Stichosome A longitudinal series of cells (**stichocytes**) that form the posterior esophageal glands in the worm genus *Trichuris*, which includes several species that are intestinal parasites in mammals.
Stochastic Having to do with or being the result of chance and random events or processes.
Stochastic event (process) An event (process) that occurs by chance; a random phenomenon such as a lightning strike.
Stochasticity The fact of occurring by chance; the condition of a system whose future cannot be precisely predicted from its

current status, even with a full knowledge of all the factors involved (due to random forces inherent in the system).
Stochastic system A dynamical system whose detailed future behavior cannot be accurately predicted, even in principle.
Stoichiometry The ratios of different elements in a material. For example, a plant tissue requires not only carbon, but also nitrogen, phosphorus, and other elements in certain **stoichiometric** proportions.
Stoichiotrophic imbalance A unique, forced trophic state in an aquatic ecosystem that develops when one nutrient, generally nitrogen (N) or phosphorus (P), but not both, is altered, either due to enrichment or management-related nutrient control. It can occur throughout the eutrophication process, depending on the enrichment sources or timing of N or P controls.
Stoma 1. The singular form of STOMATA (see below). 2. A natural opening in the body, such as the mouth. **3**. An opening in the body that is artificially created for medical purposes.
Stomata (singular **stoma**) **1**. An array of minute pores in the surface of a leaf, surrounded by specialized guard cells that regulate the degree to which the pores are open or closed. They are the medium for gas exchange across the leaf surface, as carbon dioxide and oxygen enter and water vapor and oxygen exit. 2. The entire complex including both these pores and the accompanying guard cells. Also, **stomates**.
Stomatal or **stomal** Having to do with or being part of the stomata (see previous).
Stomatal index The percentage of stomatal openings compared with epidermal cells; used with fossil plant cuticles as a proxy for past atmospheric CO_2 levels.
Storage effect A general mechanism for the maintenance of biodiversity within a single habitat, based on differences between competing species in their responses to environmental conditions. The storage effect can allow co-existence by different species, if each species reproduces successfully under the conditions favorable for it and can survive through unfavorable periods in the resistant stage (e.g., when the competing species dominates).
Strain A population of cells all of which are descended from a single cell.
Stramenopile Another term for a HETEROKONT.
Strata The plural form of STRATUM (see below).
Stratification The formation of distinct layers with different densities, which inhibits mixing. Can apply to layers of rock, levels of the ocean, or divisions of the atmosphere.
Stratigraphic Of or having to do with stratigraphy (see below).
Stratigraphic interval All (and only those) rocks formed during a specific interval of geologic time.
Stratigraphic range The strata through which a taxon is known to have been extant.
Stratigraphic section 1. An outcrop of rock (with fossils) or a drilled core. 2. A composite for a region in which fossil ranges and stratigraphic events have been summarized into a synthesized rock column.
Stratigraphy The scientific study of rock strata, especially the distribution, deposition, and age of sedimentary rocks.
Stratum (plural **strata**) **1**. A unit of sedimentary rock or soil that is distinguishable from other units on the basis of properties and/or relative position. 2. Any particular layer or level in a horizontal system, such as a hierarchical society.
Strepsirrhini One of the two recognized primate suborders, along with the Haplorrhini (see); it includes the galagos, lorises, and lemurs.
Stridulatory (stridulation) apparatus An organ of sound production based on the mechanism of rubbing one part of the body against another.
Strip intercropping See INTERCROPPING.
Strong interactor A species that has a major effect on the species (one or a few) with which it interacts. Communities and ecosystems may have various strong interactors, and such species may occur at all trophic levels. Some, but not all strong interactors are keystone species.
Structural connectivity The distance between habitat patches and the nature of the intervening landscape matrix.
Structural intricacy The complex of patterns of links or connections among species in a community that are created by biotic interactions, shared pathways of nutrient and energy flow, or phylogenetic relationships.
Stygobiont A member of one of the aquatic species that are obligate subterranean dwellers.
Stygophile A member of a species that can live and reproduce in both subterranean and surface environments.
Subarctic The ecotone (ecological boundary zone) of the Northern Hemisphere connecting the treeless tundras to the north with the taiga or coniferous boreal forests to the south. The area is characterized by the presence of scattered, deciduous or coniferous trees of low stature and is sometimes termed the **forest tundra**.
Subchelate Describing organisms in which the chela (claw-like appendage) terminal segment only folds back on the next segment as opposed to extending.
Sublittoral Another term for NERITIC.
Sub-nivean Describing an environment beneath a temporary, seasonal, or permanent covering of snow.
Subordinate Describing species that have a minor influence on ecosystem structure and function, presumably because of their lesser abundance and biomass compared to dominant species.
Subpolar Relating to or located in the regions between the polar and temperate zones.
Subshrub Another term for a SEMISHRUB.
Subsurface depletion A condition in which metabolic breakdown of organic matter from surface waters can cause depletion of dissolved oxygen concentration, leading to very low oxygen (hypoxia) or no oxygen (anoxia).
Subtropical 1. Located in the regions lying either above the Tropic of Cancer (23.5° N) or below the Tropic of Capricorn (23.5° S). 2. More generally, involving the climates and landscapes characteristic of this region. The **Subtropics** experience mild winters with little frost or snow and have a wide variety of rainfall patterns.
Succession The pattern of change in species that occupy an area over time, caused by biotic or abiotic factors that benefit some species at the expense of others.
Succulent Having fleshy tissues that store moisture.
Sulfur bacteria Bacteria that depend on the chemotrophic or phototrophic oxidation of reduced sulfur compounds for energy generation.

Sundaland The Malay Peninsula, along with Sumatra, Java, Borneo, and associated islands.
Supercontinent 1. The amalgamation of various continental masses into a single mass through continental drift. 2. Specifically, such a land mass of the geologic past; e.g., the supercontinent of Pangea (from 300 to approximately 190 million years ago) included most continental areas other than those that comprise East Asia.
Supplementation The purposeful introduction of additional organisms to an existing population to increase mean fitness or population size.
Supply chain Those stages in the production and use of a given product through which materials and energy flow can be traced.
Support(ing) services Processes that support the functioning of an ecosystem so that it can supply benefit to humans, such as soil formation or nutrient cycling. See ECOSYSTEM SERVICES.
Supralittoral 1. The portion of beaches, rocky shores, and other marine habitats that typically lie above the high tide. 2. Having to do with or occurring in this area.
Susceptible Describing a potential host for a pathogen that is neither currently infected nor immune to infection.
Suspension feeder An organism that feeds primarily on particles of organic material suspended in the water above the bottom.
Sustainability The fact of being sustainable; the ability of an individual or collective human activity to continue indefinitely without depleting the resources consumed in it, degrading the ecosystem providing these resources, or otherwise disturbing the balance between human needs and the preservation of the natural environment.
Sustainable 1. Able to endure; continuing to function over time. 2. Describing a natural system that is able to remain diverse and productive over time, based on current conditions. 3. Describing practices and policies in dealing with natural systems that are intended to ensure their viability over time; e.g., the sustainable use of a forest or fish stock.
Sustainable agriculture Agricultural practices that are environmentally sound, culturally sensitive, socially acceptable, and economically viable.
Sustainable development The process of meeting human needs of the present without damaging the ecosystems that produce these resources or compromising the ability of future generations to meet their own needs.
Sustainable forestry The management and utilization of forest resources in a way that balances human needs with undisturbed functioning of the forest ecosystem, and a long-term maintenance and sustainability of the resources and biodiversity of forests.
Sustainable use The exploitation of wildlife in a manner that avoids depletion of the resource (e.g., limited hunting, ecotourism).
Sustained yield The management and harvesting of renewable resources in a manner that does not exceed their rate of replacement or reproduction; e.g., the removal of a constant number of animals from a wild population that can be maintained through time while keeping the population at a predetermined size.
Swamp 1. A wetland dominated by woody species. 2. Any low-lying area without cultivated vegetation where water collects.
Swiddening A term for diverse types of horticulture in which a small section of forest is cut and burned to plant crops in a temporary garden.
Symbiont One of a pair of coexisting, mutually supportive organisms.
Symbiosis 1. In the strict sense, a relationship between two organisms of different species that benefits both partners; i.e., another term for MUTUALISM. 2. In the broader sense, any intimate, protracted association between organisms of different species (parasitism, commensalism, mutualism, or phoresis).
Symbiotic Having to do with or taking part in symbiosis.
Symmetry The correspondence in size, form, and arrangement of parts on opposite sides of a two- or three-dimensional object. **Bilateral symmetry** is a body plan in which similar anatomical parts (e.g., the eyes) are arranged on opposite sides of a median axis, so that the individual in effect has two matching halves.
Sympatric Describing populations, species, or taxa that occur together in the same geographical area within the dispersal range of one another.
Sympatric speciation The process in which genetic divergence between populations occupying the same geographic range leads to distinct species.
Sympatry The fact of populations, species, or taxa occurring together in the same geographical area.
Symplesiomorphy Shared, primitive similarity; a character present in all subordinate taxa of a group under consideration.
Synamorphic Having shared, derived similarity.
Synanthrope A species that lives near humans, and benefits from the types of habitats that humans create; the term does not apply to pets or farm animals. Many synanthropes are regarded as human pests, such as rats or crows. An organism that lives in this manner is **synanthropic**.
Synanthropy The fact of an organism being ecologically associated with human habitats on an ongoing basis.
Synapomorphy A character state that is derived relative to the ancestral state (plesiomorphy). Synapomorphies are special cases of homology that are evidence of monophyly among the taxa that bear them relative to taxa that bear the plesiomorphic state.
Synaptonemal complex (SC) A three-part proteinaceous structure that affects the number and distribution of chromosomal crossovers and converts these crossovers into functional chiasmata (the point of contact between paired chromatids).
Synchrony The temporal matching of periodic biological events; e.g., coordination of adult activity in an insect predator with the flowering of the plant on which it feeds. Such matching is **synchronous**.
Synergism An interaction among many factors which collectively may have a much larger (or smaller) effect than the sum of the effects of each factor acting independently. Such an interaction is **synergistic**.
Synergist A chemical used at sub-lethal concentrations to inhibit particular groups of detoxifying enzymes and therefore to implicate these enzymes in resistance.

Synlophe In numerous Trichostrongylidae (nematode worms), an enlarged longitudinal or oblique cuticular ridge on the body surface that serves to hold the nematodes in place on the gut wall.

Synonymous mutation A nucleotide change in a protein coding region that does not change the encoded amino acid.

Syntaxon (plural **syntaxa**) A category of vegetation typology based on the floristic–sociological approach (also known as the **Braun-Blanquet approach** or **method**); the basic syntaxon rank is association, which further groups into alliances, which group into orders, and which group into classes.

Systematics The area of biology that focuses on the classification of living things based on their relationships and evolutionary history.

System functions Processes that occur in an ecosystem that are typically measured as changes in the carbon or nutrient cycles regulated by decomposers, consumers, or primary producers.

Systems theory A framework for understanding the dynamics of interconnected components; can be applied to the study of complex biological systems.

Taiga 1. A Russian term applied to Eurasian conifer forests described as damp and almost impenetrable, or to a coniferous forest with no non-coniferous tree species except *Betula* and *Populus*. 2. More generally, another term for a BOREAL FOREST.

Targeted conservation Strategic land allocation and application of management practices, such as buffers, corridors, constructed wetlands, stepping stones, and reserves, to maintain species populations and ecosystem services in concert with human land use.

Target taxon The species or species group that a conservation action is focused upon.

Taungya A Burmese term for an agricultural system in which crops are interplanted with plantations of trees. As the trees grow and shade the areas, cultivation of crops is abandoned.

Taxon (plural **taxa**) A general term used to indicate groups of related organisms at any level in a taxonomic hierarchy. In the classification of evolutionary lineages, the term can refer to species, genera, families, orders, and so on. Higher taxa are those above the species level.

Taxon cycle A hypothesis proposed by E. O. Wilson to describe the common niche expansion among colonizers, and subsequent long term trend toward differentiation, coupled with isolated species narrowing their niches and restricting their ranges, resulting in eventual extinction.

Taxonomic Having to do with or based on taxonomy (see below).

Taxonomic (bio)diversity A characterization of a biota that relates to variation in the importance and taxonomic identities of taxa, estimated by components such as species richness, evenness, dominance, diversity, and rarity.

Taxonomic impediment A term for the idea that currently there is not a sufficient amount of taxonomic expertise and tools to identify and describe the world's biodiversity.

Taxonomic inflation The process by which the numbers of species in the checklist of a group increases due to a change in species concept rather than due to new discoveries of previously unknown species.

Taxonomic rank The level in the Linnaean hierarchy to which a particular taxon or group of species is assigned. For example, mammals are at the level of the class (Mammalia) and hippopotamuses are at the level of family (Hippopotamidae).

Taxonomic resolution The level of genetic variation of the taxa being considered.

Taxonomic richness The total number of species, genera, and families from a given time period or fossil excavation.

Taxonomy The classification of species and higher taxa, ultimately based on phylogeny.

Taxon sorting The argument that in certain taxa, species undergo relatively rapid speciation and extinction, while in others the species speciate and die out relatively slowly; over time this difference will mean that the highly volatile families become extinct more quickly than the less volatile ones.

Techno-ecosystem Technology-based ecosystem; a system in the contemporary world that is fundamentally distinct from natural ecosystems in features such as the use of energy sources other than sunlight (e.g., fossil fuels, nuclear power), an urbanized concentration of human population, and the generation of substantial amounts of air and water pollutants and waste materials.

Tectonic Having to do with the earth's crust, or with forces or conditions that cause the movement of this crust. See PLATE TECTONICS.

Tectonism The action of forces that disturb and dislocate the Earth's crust; earthquakes are part of this process.

Tegmina (singular **tegmen**) Thickened forewings.

TEK Traditional ecological knowledge.

Teleconnection A causal link between patterns of weather in two locations, or between two atmospheric occurrences, which are very far apart, such the El Niño Southern Oscillation, where unusually high sea surface temperatures off the west coast of South America can be connected with droughts in Indonesia.

Telson The most posterior segment of the body in crustaceans, usually flattened and often armored.

Temperate Pertaining to the climates and landscapes of the mid-latitude regions, which are seasonally warmer and cooler, with winter frost even in most coastal areas and at least partial dormancy or collapse of the vegetation.

Temperate region Any locality with at least one month of frost (for continental areas) or with one or more months with a mean temperature lower than 18° C (for maritime-influenced areas), and with at least four months with a mean temperature higher than 10° C.

Temperate virus A virus that has a high probability of integrating into the host genome rather than initiating a lytic infection.

Temporal Having to do with time; measured by or in the context of time.

Temporal dispersal The emergence of individuals from dormancy over a range of years (or another time interval), when those individuals entered dormancy in a single year. Often the years (or other time intervals) have different environmental qualities for growth and reproduction.

Temporal heterogeneity In community sampling, a variation in species capture probabilities over time; this may

arise from temporal environmental variation, migration, speciation, or other factors.

Temporal migration The avoidance of harsh environmental conditions by an individual organism that enters dormancy before conditions become harsh and emerges from dormancy when favorable conditions return.

Temporary parasite A parasite found in or on a host only for short periods.

Tepui A Venezuelan term for the sandstone table mountains of the Guayana Highland or "Lost World" region.

Terra firma Solid ground; the dry land mass of the Earth's surface.

Terra firme Non-flooded landscape in tropical lowlands, usually characterized by highly weathered nutrient-poor soils.

Terra firme forest Continuous hardwood forest of the nonflooded or upland parts of the Amazon rainforest.

Terrestrial 1. A species that lives on land (as opposed to marine or freshwater settings) for the majority of its life cycle. 2. Describing or being such a species.

Terricolous Living in or on the ground; being a soil inhabitant.

Tertiary The earlier part of the Cenozoic Era, occurring from about 65 million to 2 million years ago.

Tetrapod One of the Tetrapoda, the terrestrial vertebrate classes of amphibians, reptiles, birds, and mammals; so named because they all (at least primitively) possess four legs.

Thelytoky A reproductive mode in which unfertilized eggs develop into diploid females. An organism reproducing in this manner is **thelytokous**.

Therapod One of the Therapoda, the so-called beast-footed dinosaurs, a diverse group of bipedal animals including huge carnivores such as *Tyrannosaurus rex* and also small nonflying animals that are the ancestors of modern birds.

Therapsid One of the Therapsida, an order of reptiles that existed during the Late Paleozoic and Early Mesozoic, from which mammals are believed to have evolved.

Thermally tolerant Describing organisms able to live at temperatures significantly higher than the regional norm. They can also exist at cooler temperatures, but may not compete well in the latter situation.

Thermal opportunist An organism that has developed life history characteristics that permit the exploitation of temporary cooler spots in thermal systems.

Thermal system An outflow of geothermally heated water, especially one at the surface of the earth where light is present.

Thermal vent Geothermally heated water issuing from cracks in the ocean floor. Very high temperatures and pressures and the complete absence of light are characteristic of these vents.

Thermophile Heat lover; an organism that grows optimally at temperatures between 50° and 80^0 C. Such an organism is **thermophilic**. Compare HYPERTHERMOPHILE.

Thermophily The fact of being adapted to live at high temperatures and (usually) unable to survive at lower temperatures.

Thoracopod An appendage on the thorax (paired in crustaceans).

Threatened Facing a relatively high risk of extinction in a definable time period. In ranking systems for extinction risk, it is typically a category less critical than ENDANGERED.

Threatened species A species that faces a significant risk of extinction in the near future over all or a significant portion of its range.

Three-taxon statement The idea that two species (or taxa) are more closely related to one another than either are to a third; the most basic hypothesis in cladistics.

Threshold theorem In epidemiology, the principle that if the density of susceptible individuals in a population falls below some critical threshold, then a disease may not be able to maintain itself in the population.

Timber line The boundary of closed, tall forest with timber-size stems; it commonly occurs at an elevation that is 50–150 m lower than the tree line.

Tipping point The point at which a complex system goes into disequilibrium and is replaced by a new system; e.g., the transitional point separating two alternate regimes or configurations in the structure and function of an ecosystem.

Token cue An environmental cue that induces a state of dormancy in certain animals, such as reduced day length. The cue serves as a reliable indicator of a coming onset of harsh environmental conditions, but is not in itself harsh.

Tokogeny Birth relationships responsible for reticulate patterns of relationships within and among populations.

Tolerance An individual's capacity to sustain damage by an enemy with limited decrease in fitness.

Top-down 1. Describing a process in which feeding by higher trophic-level organisms has cascading effects on lower trophic levels; e.g., when fish (predators) consume zooplankton (herbivores) and, by lowering the numbers of these herbivores, allow increased densities of photosynthetic phytoplankton (primary producers). 2. Describing impacts or controls on urban biodiversity that originate from human actions at larger scales, as at the level of a city or above. Thus, **top-down effect** or **force**. Compare BOTTOM-UP.

Topkill Loss of the aerial biomass in trees or other plants as a result of fire, although the plant as a whole still survives and can resprout from root-stocks. Seedlings and saplings are particularly vulnerable to topkill.

Top predator See APEX PREDATOR.

Torpor A condition, usually in birds and mammals, when the body temperature falls a few degrees below the ambient temperature for a short period of time. It differs from HIBERNATION in the extent to which the body temperature falls and the length of the resting state.

Total allowable catch The level of permitted catch established by fishery regulations.

Tourism Travel for leisure, recreation, or vacation; for economic statistics, generally only overnight travel is included. See also ECOTOURISM.

Trace gas A gas present in the atmosphere in low mixing ratios (typically less than a few ppm). Some trace gases, including methane, nitrous oxide, and ozone, are greenhouse gases. Others are reactive in the atmosphere and influence the greenhouse effect indirectly. For example, carbon monoxide, produced by internal combustion engines and certain industrial processes, competes with methane for the available oxidizing capacity of the atmosphere, and so an increase in carbon monoxide emission leads indirectly to a higher methane concentration.

Tracheae 1. In terrestrial vertebrates, a tube connecting the pharynx or larynx to the lungs, allowing the passage of air. 2. In invertebrates, a system of hollow, branched or unbranched air-conducting tubes used for respiration, opening via abdominal spiracles. They may or may not extend into the cephalothorax or legs.

Tracheophyte A vascular plant; i.e., one having tissues that conduct water, minerals, and photosynthetic products through the plant.

Trade-off A negative correlation between traits, such that a benefit due to changes in the value of one trait is associated with a cost produced by changes in the value in another trait.

Traditional Following a pattern that has continued over time; according to beliefs, customs, practices, and so on that have persisted from generation to generation.

Traditional agriculture An indigenous form of ecologically based agriculture resulting from the coevolution of local cultural and environmental systems; generally characterized by energy sources such as human and animal power, hydropower, or wind as opposed to elaborate machinery, the use of biological fertilizers and pest controls as opposed to chemical ones, and crop variety as opposed to monoculture. Traditional agriculture has significantly less environmental impact than INDUSTRIAL AGRICULTURE (see).

Traditional ecological knowledge (TEK) A cumulative body of knowledge, practice, and belief, evolving by adaptive processes and handed down through generations by cultural transmission, about the relationship of living beings (including humans) with one another and with their environment. TEK is applied by indigenous and other peoples in their interactions with their habitats and in their system of natural resource use and management. Also known as **traditional environmental knowledge.**

Traditional peoples Peoples with cultures that differ from those of the mainstream of a national population, typically having distinct languages and locally evolved resource management systems.

Traditional society A group in which knowledge, practice, and belief are handed down through generations largely by cultural transmission. The tradition itself evolves by adaptive processes, but not all tradition is necessarily adaptive.

Traditional variety See LANDRACE.

Tragedy of the commons A process in which an open access resource is overexploited because individual users cannot expect to realize the potential benefits of resource conservation for the community in general.

Trailing edge The dynamic margin of a species' range where it is becoming locally extinct, causing the range to retract.

Trait A quality or characteristic that an organism may possess through inheritance.

Transaction costs 1. The costs associated with negotiating an economic exchange. 2. Specifically for a terrestrial conservation effort, the costs in addition to the price of a transfer of property rights for a given parcel of land, such as the costs of property search, negotiation with individual landholders, and approval for title transfer. For example, carbon sequestration projects involving afforestation or reforestation can be beneficial for conservation, but high transaction costs often limit their viability.

Transgenic Having a gene or genes that were transferred from another organism (**transgenes**), most often by means of biotechnology.

Transient species Describing plant species that are present as scattered seedlings or small immature individuals; many of these species occur as dominant or subordinate species in neighboring vegetation associated with different environmental conditions or management regimes.

Translocation The intentional movement of organisms by people from one or more locations to other locations.

Transmission dynamics Changes in the rates of pathogen transmission through time.

Transovarial transmission The vertical transmission of a pathogen through its passage from mother to offspring.

Transpiration The process by which vascular plants take up water through the roots, transport it through the xylem, and evaporate it from the surface of the leaves.

Transport host A host that harbors sexually immature stages of a parasite that do not develop.

Transposon A segment within a chromosome that replicates itself by transposition to a new location within a host genome, or from a genome to other extrachromosomal DNA in the cell such as a plasmidorviral genome. Also known as a **transposable element**.

Tree A cladogram (diagram of organismal relatedness) or a cladogram interpreted in more evolutionary detail.

Tree line The high-elevation and/or high-latitude limit of forested landscape, usually fragmented at this point. Most often there is no literal "line" visible in the landscape, so tree line position represents a convention. Also spelled **treeline**.

Tree line ecotone The whole transitional area from the lower timber line (see) to the higher tree species line (see next).

Tree species line The highest point above the tree line at which individual trees or small groups of trees are found.

Triacylglycerol An ester of glycerol and three fatty acids. The commonest lipid storage molecule in animals and green plants.

Triage A system of prioritization for making decisions when resources are scarce and the need for responses is widespread. The *tri-* prefix denotes the concept that priorities can be separated into three groups: those situations where conditions do not require intervention; those where intervention is likely to be futile, and the intermediate group that could benefit from intervention (this last being the focus of prioritization). [Originally applied to a French system of battlefield medicine in World War I that divided casualties into those likely to live without immediate treatment, those likely to die even with treatment, and those who could survive if given immediate treatment.]

Trichobothria (singular **trichobothrium**) In arachnids and various insects, long, delicate, slender setae set in broad, shallow innervated sockets in the cuticle. Trichobothria are sensitive to vibration or near-field air movement and are a major sense organ of arachnids.

Triramous Relating to or having an extension of the body (usually an appendage) with three branches; e.g., triramous antennae have three main branches or flagellae.

Tritomy A condition of three undifferentiated branches or clades. Also, **trichotomy**.

Trochophore A type of larva characteristic especially of annelids and mollusks, swimming freely by means of a ciliated girdle around the middle.
Troglobiont Terrestrial species that are obligate subterranean dwellers; the term is sometimes used for aquatic species as well.
Troglobitic Describing cave-dwelling organisms that are adapted to life in complete darkness.
Troglobite An organism whose entire life cycle takes place in a cave or other subterranean environment. Contrasted with a TROGLOPHILE (see below).
Troglomorphic Pertaining to the morphological, behavioral, and physiological characters that are convergent in subterranean species.
Troglophile A cave lover; a terrestrial species that lives in a cave or other subterranean environment but that also can live and reproduce in surface environments; sometimes used for aquatic species as well. Such an organism is **troglophilic**.
Trophic Relating to feeding; describing types of food consumed and patterns of feeding behavior.
Trophic cascade The effect of predatory feeding on prey that propagates down more than one link in a food web. Trophic cascades cause inverse patterns in the abundance or biomass of trophic groups at successive levels of a food web.
Trophic complexity The number and types of organisms that feed at different trophic levels within a community.
Trophic downgrading Ecological and environmental consequences associated with losses of apex predators from ecosystems.
Trophic input Energy entering a community via pathways other than local primary production, and often at higher levels in the food chain. For example, nutrients from salmon carcasses are a periodic trophic input to the forest community adjacent to salmon streams.
Trophic interaction A feeding relationship between two species; these include predation, herbivory, parasitism, bacterivory, frugivory, or any other interaction that involves individuals of one species consuming individuals or parts of individuals from another species.
Trophic level An abstract classification to describe subsets of species that acquire energetic resources in a similar way on a subset of species (e.g., top carnivores feed on primary carnivores which feed on herbivores which feed on primary producers). In natural systems, most species do not feed strictly on the level below them, making the concept of trophic level a difficult term to assign operationally to species.
Trophic status A ranking system for aquatic ecosystems, based on the amount of organic production and nutrient (N, P) levels.
Trophic web Another term for a FOOD WEB.
Trophogenic Describing a region where net production of organic matter occurs by photoautotrophy or chemoautotrophy.
Tropholytic Describing a region where respiration and decomposition of organic matter occur in the absence of primary production.
Tropical 1. Located in the region lying between the Tropic of Cancer (23.5° N) and Tropic of Capricorn (23.5° S). 2. More generally, involving the climates and landscapes characteristic of this region. The **Tropics** are essentially frost free in the lowlands and permit biological activity as long as water is available.
Tropical dry forest A type of forest found in tropical to subtropical regions that has distinct rainy and dry seasons. Many tropical dry forest plants are adapted to withstand high temperatures and seasonal droughts.
Tropical rainforest A forest that occurs below 1000 m in elevation, experiences high, relatively constant temperatures, and receives at least 200 mm of rainfall per year.
TRY A global database of plant functional traits, maintained by the Max Planck Institute for Biogeochemistry in Jena, Germany and governed by an international steering committee.
Tuberculum interglenoideum An anterior projection of the first (cervical) vertebra in salamanders. It bears articular facets that insert into the foramen magnum of the skull and provide additional articulation points between the skull and the vertebral column.
Tundra The vegetation characteristically occupying the Arctic.
Turnover A measure of the amount by which the species composition changes among subunits in a data set.
Type The specimen, culture, or other element on which the scientific name of an organism is based and that fixes the name's application.
Type I community An assemblage of species in which the richness is a constant proportion of the number of species occurring in a larger geographic unit where the community is embedded.
Type II community An assemblage of species in which the richness is independent of the number of species in a larger geographic unit where the community is embedded.
Typification The practice of designating a single specimen (or, formerly, a series) as the name-bearer for a species; or a species for a higher taxon, especially genera.
Ultraviolet radiation Radiation with wavelengths shorter than violet light and with more energy.
Umbrella species A species with large habitat needs or other requirements whose conservation results in many other species also being conserved at the ecosystem or landscape level, thus it acts as an "umbrella" protecting these species.
Uncultured Describing prokaryotic organisms whose presence has been detected by molecular methods in the environment but that have not been cultured under artificial laboratory conditions.
Understory The broad spectrum of plants at the ground level of forests that often provide forage for grazing animals. These transitory plants are often relatively sparse in dense forests with closed canopies.
Underutilized Describing a species whose potential for contributing to food security, health (nutritional/medicinal), income generation, and environmental services has not been exploited.
Unguligrade 1. Walking only on a hoof or tip of the digit. 2. An organism that walks in this manner; i.e., the hoofed mammals such as deer, horses, and cattle. Compare DIGITIGRADE, PLANTIGRADE.
Uniramous Relating to or having an extension of the body (usually an appendage) with one branch.

Unity of type Similarities among organisms leading diverse ways of life under diverse conditions of existence, going beyond any functional need for similarity. Under the theory of descent with modification, these similarities result from common ancestry.

Unplanned biodiversity Soil biota, herbivores, carnivores, decomposers, and any other species that naturally exist in or colonize an agroecosystem, as opposed to crops and livestock purposefully introduced and maintained there by humans (planned biodiversity).

Uptake capacity See NUTRIENT UPTAKE CAPACITY.

Upwelling An ocean phenomenon in which cooler, more nutrient-rich water rises up from the bottom of the ocean to the surface. This occurs where currents of contrasting temperatures meet. The extra nutrient influx allows for specific and rich **upwelling ecosystems** in these areas (e.g., off the coasts of Chile and Peru, and southwest Africa).

Urban ecology The study of urban systems from an ecological perspective; an emerging field within ecology that strives to understand human interactions in ecological systems in and around urban areas and to develop theories and analyses that include human communities as fundamental components of ecological systems.

Urbanization 1. A process in which an area becomes more urban; i.e., increases in population, building density, and so on. 2. The relocation of people to large cities from rural areas and smaller towns and villages.

Urban sprawl Urban development that occurs at a relatively low population density and/or occupies a large amount of land.

Use values Values that are obtained by using a natural resource, such as timber, fuelwood, water, or landscapes.

Utilitarian Describing the school of conservation philosophy that emphasizes the value of the natural world in contributing to human well-being, especially in terms of economic standard of living.

Vapor pressure deficit The difference between the water vapor content of the air and the saturated water vapor content of the air at its current temperature; this is the driving force of transpiration.

Variety See CULTIVAR.

Varzea Brazilian term for the floodplain of the whitewater rivers of the Amazon basin.

Vector An animal, typically an arthropod, that transmits pathogens from one host to another; e.g., mosquitoes are vectors of malaria.

Vegetation The total plant cover of an area.

Vegetation megazone A large-scale vegetation complex characteristic of a zonobiome.

Vegetative Describing a form of asexual reproduction in plants; a process by which new individuals arise without production of seeds or spores. Thus, **vegetative reproduction, propagation, multiplication**, and so on.

Ventral The part of an organism that is the "front" or lower part of the body. Contrasted with DORSAL which is the "back" or upper part.

Vermiform Worm-shaped, with a tapering form at both the posterior and anterior.

Vertical transmission The transmission of pathogens across generations of hosts.

Vestigial Describing an organ or structure that is present only in rudimentary form (probably lost from a previous condition).

Viable 1. Having life; able to live and grow. 2. Specifically, describing a population deemed to have a reasonable chance of long-term persistence; the sense of what is a reasonable chance of survival and what constitutes a long term can vary according to the defining entity. The fact of being viable is **viability**.

Vibratory papillae In certain insects, mobile, grooved, rod-like appendages arising from the distal edge of the first thoracic segment, used for communicating.

Vicariance The existence of closely related taxa or biota in separate, disjunct areas, which have been separated by the formation of a natural barrier (vicariance event; see next).

Vicariance event A historical event that isolates species' populations and leads to speciation (e.g., the closing of the Isthmus of Panama); usually considered in a geological context, but human activities also generate such events. Also, **vicariant event**.

Virad A suffix denoting viruses that belong to a certain order (e.g., viruses in the order Picornavirales are picornavirads).

Viral Having to do with or caused by a virus.

Viremia A concentration of viruses in the blood of a host.

Virid A suffix denoting viruses that belong to a certain family; e.g., viruses belonging to the family Phycodnaviridae are picornavirids.

Virion An individual viral particle.

Virulence The degree to which a parasite reduces the probability of survival or the reproductive capacity of its host.

Virulent Capable, or highly capable, of causing disease.

Virus A genetic element containing either DNA or ribonucleic acid (RNA) that can replicate only in cells but is characterized by having an extracellular state; an infectious agent causing disease in all forms of organisms. 2. A type of disease or infection cause by such an agent; e.g., Ebola virus, West Nile virus.

Viviparous 1. Describing reproduction in which the young are born alive. 2. Describing an organism with this mode of reproduction; e.g., most mammals. The fact of reproducing in this way is VIVIPARITY. Compare OVIPAROUS; OVOVIVIPAROUS.

VOC Volatile organic compound; many VOCs are emitted by plant leaves, of which the most abundant is the unsaturated hydrocarbon isoprene. VOCs have various functions in plants, including protection against heat stress damage and damage by insect herbivores.

Volunteer (vegetation) A plant or plants growing on its own instead of being deliberately planted by a farmer; usually applied to a desirable plant rather than a weed.

Voucher A representative specimen of a plant or an animal that is properly collected, prepared, and preserved in a herbarium or museum to facilitate identification of the species.

Vulnerable Facing a high risk of extinction in the wild.

Wadi A gully, stream bed, or other water course that is dry except during a rainy season; used especially of such features in northern Africa and southwest Asia.

Wallacea Lands east and north of Borneo, west of New Guinea and east of Wallace's Line (see next), including the Philippines, Sulawesi, Lombok, Sumbawa, Sumba, Timor, the

Moluccas (e.g., Halmahera and Seram), Flores, and the other islands of Nusa Tenggara.

Wallace's (Wallace) Line A hypothetical line marking the division between the Oriental and Australasian zoogeographic regions. [First depicted by the English naturalist Alfred Russel Wallace.]

Water-holding The ability of soil to retain water; e.g., sandy soils have very low water-holding capacity, while clay soils have higher capacity.

Water pollution Lowering of water quality due to input of sewage, pesticides, agricultural runoff, and industrial wastes that can harm aquatic plants and animals.

Water quality standards Risk-based requirements that set site-specific allowable pollutant levels for individual water bodies, such as rivers, lakes, streams, and wetlands. These standards are set by designating uses for the water body (e.g., recreation, water supply, aquatic life, agriculture) and applying certain criteria to protect the designated uses.

Watershed The drainage basin contributing water, organic matter, dissolved nutrients, and sediments to a stream or a lake.

Water-use designation The appropriate water uses specified for a given body of water, such as public water supply, protection of fish, shellfish, and wildlife, or recreational, agricultural, industrial, or navigational purposes.

Water-use efficiency (WUE) a measure of the amount of photosynthesis or growth per unit of water lost in transpiration.

Weak interactor A species having little effect on other species, at least under average conditions. Under some circumstances, weak interactors may occupy important roles in ecological communities as a result of changes that lead to temporary increases in their abundance, size, or biomass.

Weed An unwanted plant that interferes with the growth of desirable plants, especially one that is unusually persistent and harmful.

Weed control The process of reducing or suppressing weeds in a defined area to an economically acceptable level, without necessarily eliminating them.

Weevil A member of the beetle family Curculionidae.

Wetland A terrestrial ecosystem with a water table that is permanently close to the surface.

Wetland bank A site where wetlands and other aquatic resources are restored, created, enhanced, or preserved.

Wetland creation The conversion of a persistent upland or shallow water area into a wetland by human activity.

Wetland restoration See RESTORATION.

White-water A term for Amazonian rivers that are muddy with much suspended sediment and are neutral or only slightly acidic.

Wild Not domesticated; describing those species that have not been brought under human management.

Wilderness A large area that remains essentially unmanaged and unmodified by human beings. Also called a **wildland**.

Wildland fuel Any live or dead biomass available for burning.

Wildlife All nonhuman and nondomesticated animals.

Wildlife-friendly Describing farm management practices as benign to wildlife as possible; can include reduction in pesticides and chemical fertilizers and retention of patches of non-farmed habitats and less-intensively farmed semi-natural habitats.

Wildwood Wholly natural forest not affected by human activities such as agriculture and pasturage, widespread in prehistoric times (including earlier interglacial periods) and still surviving in remote places.

Willingness to pay The highest payment a person would make in return for a good or service.

Woodland An ecosystem in which the mature overstory tree or tall shrub cover makes up a high percentage of the area. Typically, a well-developed herbaceous understory is present. The mature tree cover is usually greater than 60 percent.

Wood-pasture A human-managed ecosystem combining trees for fuelwood and timber with grazing land for domestic animals.

Worker A female in a social insect colony that is not able to reproduce; so called because they perform "helping" tasks in the colony, such as foraging for food or caring for larvae.

WUE Water-use efficiency.

Xenobiotic 1. A toxic substance not naturally produced within organisms. 2. Having to do with or being such a substance.

Xeric Describing a dry environment.

Xeromorphic Describing a form that has developed in response to highly arid conditions.

Xylem Water-conducting tissue in the stem or transport roots of vascular plants.

Zero-growth isocline In a graph with axes describing factors important to population growth (e.g., resource abundance), a line along which a population's growth rate is zero.

Zonation The tendency of climate, soil, and natural landscape types to occur in distinct latitudinal zones (e.g., tropical, subtropical, and temperate), as influenced by the global atmospheric circulation system.

Zonobiome A broad ecological topographical unit characterized by a certain climatic pattern.

Zoogeographical region or province One of the major geographical divisions of the world, identified for the study of the distribution of land mammals. They are the Palearctic (Europe, North Africa, Asia north of the Himalayas), the Nearctic (North America), the Neotropical (South America), the Afrotropical (Africa south of the Sahara), the Oriental (Asia south of the Himalayas), and the Australasian (Australia, New Zealand and nearby islands). The latter two feature a zone of overlap known as Wallacea. Antarctica constitutes an additional region.

Zoogeography The study of the geographical distribution of animal life on Earth.

Zoonosis A disease of humans caused by pathogens that proliferate within and are transmitted from nonhuman vertebrate animals; e.g., plague, Lyme disease, West Nile virus. Such a disease is said to be **zoonotic**.

Zooplankton Those animals that are found passively drifting or weakly swimming in the water column. They can be divided into two major categories: **holoplankton**, which spend their entire lives as plankton, and **meroplankton**, which spend part of their life cycle as plankton and part on the

sea floor as benthic invertebrate larvae or asnekton (e.g., fish larvae).

Zooprophylaxis The use of wild or domestic animals to divert potential pathogen vectors from feeding on humans.

Zooxanthellae A diverse group of symbiotic, photosynthetic dinoflagellate algae associated with corals and other tropical marine invertebrates. Such organisms are **zooxanthellates**.

Index

Notes
Cross-references terms in *italics* are general cross-references, or refer to subentry terms within the main entry (the main entry is not repeated to save space). Readers are also advised to refer to the end of each article for additional cross-references – not all of these cross-references have been included in the index cross-references.

The index is arranged in set-put style with a maximum of four levels of heading. Major discussion of a subject is indicated by bold page numbers. Page numbers suffixed by *T* and *F* refer to Tables and Figures respectively. *vs.* indicates a comparison.

Where index subentries and sub-subentries pertaining to a subject have the same page number, they have been listed to indicate the comprehensives of the text.
